The very low dosage given in the first clinical study was based on the hypothesis that the oncolytic virus should be able to replicate and hence produce a higher dose within the tumor. In the second clinical study evidence of viral replication in human high grade glioma was examined. Twelve patients with high grade malignant glioma received $10^5$ p.f.u. of HSV mutant 1716 by direct intratumoral stereotactic injection [156]. Tumor resection was carried out 4–9 days after treatment and the tissue was examined for presence of HSV DNA by PCR, southern blotting immuno-histochemistry and the presence of infectious viral particles by plaque assay. Results from plaque assays revealed the presence of infectious viral particles in resected tumors from two out of twelve patients. Southern blot analysis confirmed that the recovered virus was HSV mutant 1716. HSV DNA was detected by PCR at the site of injection in 10 out of the 12 patients while specimens from distal tumor sites of only four patients were found to be positive for HSV DNA [156]. Immunohistochemistry of tissue samples revealed positive staining for HSV proteins in tumor tissues from two of the twelve patients. The absence of detectable viral DNA protein or infectious particles in some specimens could be attributed to tissue sampling errors owing to non-uniform spread of the injected virus throughout the tumor tissue, or simply reflect the need to improve current methods used for detection. Nevertheless the study demonstrated evidence of HSV presence in tissue without any obvious signs of toxicity [156].

Based on these studies another clinical trial in the UK was initiated to test the therapeutic efficacy of the HSV mutant 1716 in human glioma patients. Despite the lack of toxicity seen in those trials, due to paramount safety concerns the therapeutic dose given to the patients was not increased as would have been done for clinical trials with a chemotherapeutic agent. A total of 12 patients who had been diagnosed with high grade recurrent (six patients) or newly diagnosed (six patients) glioma

underwent gross tumor resection. After the initial tumor debulking, $10^5$ p.f.u of HSV mutant 1716 was injected into 8–10 sites within the tissue surrounding tumor cavity. The patients were carefully monitored with a comprehensive clinical work up including immunological, hematological (full blood count with white cell count differential) and biochemical (urea, electrolytes, liver function tests, and bone profile), and neurological examinations. The lack of any virus related toxicity in this study considerably strengthened the safety profile of this approach even though the virus had been injected into tissue involving functioning brain. The expected median survival for patients with GBM is 1 year from the time of initial diagnosis and only 3–6 months following diagnosis of a recurrent tumor. One patient with a recurrent tumor and two patients diagnosed with primary GBM survived for more than 22, 18, and 15 months, respectively. The patient who survived for more than 22 months was diagnosed with a recurrent tumor but was disease free at 22 months. However, a causal relationship between response and viral treatment could not be established. This study demonstrated that HSV1716 can be injected into the normal brain of individuals without any ensuing toxicity.

The therapeutic potential of HSV1716 has also been assessed in five patients with stage 4 metastatic melanoma. In each patient paired distinct nodules were injected with either dilutent or $10^3$ p.f.u of HSV 1716 [157]. Flattening of previously palpable tumor nodules was seen after direct injections of HSV1716 in one patient, and in three patients there was microscopic evidence of tumor necrosis. These findings suggest that HSV1716 is non-toxic and could be of therapeutic benefit in patients with cancer.

## 5.7 Future of HSV 1716

HSV1716 is currently being pursued by Crusade Laboratories, Glasgow, UK. The company has been granted orphan drug status in Europe for "the use of HSV mutant 1716 in the treatment of glioma". Crusade laboratories have received regulatory approvals to initiate a Phase III trial, for glioma patients. Glioma patients with a first recurrence after surgery will be randomized into one of two treatment arms: HSV1716 or conventional chemotherapy. Satisfactory results in this trial could lead to a license and marketing authorization in glioma. The company is also pursuing Phase I/II safety and biological activity studies in patients with ovarian carcinoma and unresectable hepatocellular carcinoma [158].

## 5.8 Second Generation Multi-Mutated Oncolytic Viruses: G207

In parallel with the HSV mutant 1716 clinical studies in UK, a doubly attenuated oncolytic HSV, has also been investigated in human patients in the USA. Owing to the overriding concerns of safety arising from the use of singly mutated viruses, oncolytic viruses with multiple genetic defects were created for the treatment of cancer. G207, is one such virus that has deletions at both gamma 34.5 (RL1) loci and an in-frame and gene disrupting insertion of *E. Coli* beta galactosidase gene within the ICP6 gene (UL39), making it replication-competent in dividing cells. This minimizes the

chances of G207 reverting to wild type, and maintains an attenuated neurovirulence, temperature sensitivity, as well as ganciclovir hypersensitivity [159]. The insertion of β-galactosidase permits easy detection of cells harboring the virus in infected tissue. Pre-clinical testing of this virus was performed in nude mice harboring subcutaneous or intracerebral gliomas. Intraneoplastic administration of the virus resulted in slower tumor growth and/or prolonged survival [159].

Pre-clinical toxicity studies of G207 also found it to be avirulent upon intracerebral inoculation of mice and HSV-sensitive non-human primates. Shedding and biodistribution of G207 was determined in new world owl monkeys (*Aotus nancymae*) after intracerebral inoculation of $3 \times 107$ p.f.u. of clinical grade virus. Even after 2 years of inoculation G207 DNA was found to be restricted to the brain, although no infectious viral particles were obtained. Histopathology of the necrospied tissue revealed normal brain even at the site of injection. Absence of virus DNA in tears saliva and vaginal secretions indicated lack of viral shedding and suggested that strict biohazard management of G207 patients may not be required. Together these results implicate the possibility of considering mutimutated oncolytic viruses such as G207 for clinical evaluation for the treatment of cancer.

Safety of intracerebral inoculation of G207 in humans was determined in a dose escalation study in patients suffering from recurrent malignant glioma. The protocol was approved by the Recombinat DNA Advisory Committee of the National Institute of Health and Food and Drug Administration. The trial was initiated with the administration of $1 \times 10^6$ p.f.u. of G207, into the brains of three patients post-tumor resection. After 28 days of observation to confirm lack of acute toxicity three patients were then recruited into the next cohort and were treated with the higher dosage. In the last cohort the patients were treated with $1 \times 10^9$ p.f.u of G207 inoculated into five sites after surgical resection of the brain tumor. No toxicity which could be directly attributed to the infectious virus was noted in this study. This study suggested that G207 can be safely inoculated into human brain tumors upto doses of $1 \times 10^9$ p.f.u. without any adverse events. This agent is currently being investigated for efficacy in Clinical trials. Future studies will reveal the efficacy of combining oncolytic viruses with radiation and chemotherapy in patients.

# *Karl Fischer Titration: Determination of Water Content in Pharmaceuticals*

**Dr. Katrin Schoeffski and Helga Hoffmann**
*Sigma-Aldrich Laborchemikalien GmbH, Seelze, Germany*

## 1 BASICS

The Karl Fischer titration is based on the reaction from iodine with sulfur dioxide in alcohol in the presence of water.

During the determination water reacts stoichiometric with iodine in presence of an excess of sulfur dioxide. The reaction investigated thoroughly by Scholz (1) proceeds in two steps:

$$\text{1st step:} \quad SO_2 + \text{R-OH} + B \Leftrightarrow \text{R-}SO_3^- + BH^+ \tag{1a}$$

$$\text{2nd step:} \quad RSO_3^- + I_2 + H_2O + 2B \Leftrightarrow RSO_4^- + 2BH^+ + 2I^- \tag{1b}$$

B = Base as imidazole

One mole iodine reacts with one mole water.

***FIGURE 1*** *pH dependence of the reaction rate constant of the Karl Fischer titration (2).*

## 2 IMPORTANCE OF THE pH

As shown in the equation mentioned above, protons were generated and have to be buffered during the Karl Fischer reaction. So the reaction rate of the Karl Fischer reaction is dependent of the pH. In Fig. 1 this dependence is shown.

A high reaction speed is necessary for the Karl Fischer titration since a long titration time enlarges the error caused by invading humidity from outside. In Fig. 1, it can be seen that a pH lower than 6 should be avoided since the titration is too slow. On the other hand at pH values higher than 8 a side reaction occurs. Therefore, the base used in Karl Fischer reagents is very important. It must be strong enough to push the equilibrium of the reaction Eq. 1b to the right side. But the base must also not too strong, since beginning at pH 8 the iodine starts to decompose and pretends a higher water content or hinders the system to find a stable end point. Imidazole and its substitutes have been found as ideal Karl Fischer bases. They keep the pH value of Karl Fischer reagents in the ideal range of 5–7. Strong acid or basic samples can also influence the pH in the titration vessel. To hold the pH value constant a buffer is necessary. For acids the use of imidazole as buffer has been successful, salicylic acid or benzoic acid are used for strong basic samples to keep the pH on an ideal level (3).

## 3 SIDE-REACTIONS OF SAMPLES WITH KARL FISCHER REAGENTS

Due to the nature of the Karl Fischer reagent, a variety of side-reactions of the reagent with the sample are possible. The Karl Fischer reagent consists of iodine, an organic base and sulfur dioxide in an alcoholic solvent. The first group of side-reactions occurs of substances, which undergo a redox reaction with the iodine/iodide complex as peroxides or unsaturated hydrocarbons. Several methods can hinder the oxidation. The change of the pH may be useful, masking of double bonds another possibility.

Whether a sample reacts with iodine can be found out easily when a methanolic iodine solution is dropped into the sample. In case of decoloring a reaction takes place and a special sample preparation is necessary.

Another possible side-reaction is the reaction with sulfur dioxide. The bisulfite addition of aldehydes is a common chemical reaction, which belongs to this class. This is one of the rare cases, where the water content found can be too low. The aldehyde, ingredients of the reagent and some of the water of the sample form a "bisulfite adduct". In this case dedicated reagents, a suitable titration agent and a dedicated medium for the titration vessel as well have to be used. The most frequent side-reaction of a Karl Fischer reagent during Karl Fischer titration is the formation of acetals and ketals respectively, from carbonyl compounds. The reaction forms water, which is also titrated, resulting in vanishing end points, and an erroneously high water content occurs. In some cases no end point can be found. This side-reaction can be suppressed when methanol is replaced by other suitable alcohols. Depending on the reactivity of the carbonyl compounds in the sample also a titration reagent developed especially for the titration of ketones and aldehydes is necessary. Coulometric titration is NOT recommended for water determination in these samples.

## 4 KARL FISCHER TITRATORS

Several manufacturers of laboratory equipment offer special Karl Fischer titrators. The end point of the titration is detected potentiometrically. On a double-platinum electrode a defined current is laid, the required potential is measured. When the measured potential goes rapidly down to a very low voltage the end point is reached. Commercial available volumetric Karl Fischer titrators work with one and two component reagents as well. Pre-titration starts automatically, and the result is calculated and shown on a display. Also Karl Fischer coulometers are offered. They automatically dry the coulometric cell after addition of the reagent and keep it dry during the stand-by. In both types of titrators standard methods and calculations are already implemented. For automation sample changers can be used. Karl Fischer ovens can be connected to many of the commercial available volumetric and coulometric Karl Fischer titrators. And at last, documentation systems are also available which enables the user to keep all records according to quality and legislative requirements.

## 5 KARL FISCHER REAGENTS

Decades ago, laboratory personnel were expected to prepare Karl Fischer reagents of their own. The unpleasant smell of pyridine, the rapid loss of titer, and the great ineffectively made this duty very unpopular so most laboratories have changed to commercial reagents in the meantime. These reagents have surpassed the popularity of home-made Karl Fischer reagents in many application areas. They contain more effective bases and are characterized by a rapid course of titration. In addition a more

stable end point is caused by the higher reaction speed. A better accuracy is also reached with modern high-speed reagents. An additional benefit for the user is caused since the reagent suppliers improve the safety for the laboratory personnel by eliminating toxic and unpleasant ingredients.

The following reagent depictions give also an overview about the typical "Karl Fischer nomenclature" for the various types of Karl Fischer titration techniques.

The volumetric one-component titration reagent is called "Composite". It contains all active ingredients iodine, sulfur dioxide, and a suitable mixture of bases in an appropriate solvent. The number 5, 2, and 1, respectively, behind the "Composite" gives the titer in mg/mL water. In the titration vessel a "Working Medium" is filled. This can be pure methanol or a ready-made mixture of various solvents, e.g., to improve the solubility of the sample or to suppress side-reactions. Buffer can also be included.

For the two-component titration a solution of iodine in a suitable alcohol called "Titrant" is filled into the buret, the titration vessel is equipped with the "Solvent", a mixture of sulfur dioxide and the base in a suitable alcohol.

For coulometric titration the anolyte or "Coulomat A" is filled into the anodic compartment of the coulometric cell. It consists of iodide, sulfur dioxide, bases, and appropriate solvents. The catholyte or "Coulomat C" is filled into the cathodic compartment of the diaphragm cell and consists of a special mixture of salts in methanol, which can be reduced in a cathodic electrochemical reaction.

Special reagents for certain groups of samples can also be identified by the name. A "K" indicates reagents for ketones and aldehydes. "Oil" displays the suitability for non-polar samples. The suffix "E" indicates a reagent based on ethanol, which is less hazardous and more environmentally friendly. "Standards" are substances or solvent mixtures with a dedicated water content for the calibration of Karl Fischer reagents, for the control of instruments according to ISO 9000, for the validation of procedures and for the suitability tests according to Ph.Eur. as well.

The latest developments are reagents based on ethanol. This solvent is significantly less toxic than methanol and has better solubility properties for non-polar samples. (4)

## 6 STANDARD PROCEDURES FOR KARL FISCHER TITRATIONS

As already mentioned the titration can be performed volumetrically and coulometrically. Typical for the Karl Fischer titration is the so-called pre-titration. Since humidity is everywhere in the atmosphere, the equipment and also reagents can never be absolute water-free. When a Karl Fischer instrument is filled with the reagent or working medium, in the first step the cell must be titrated to dryness. In the second step the sample is added and its water content is titrated.

In the volumetric one-component titration the reagent must be filled into a buret. In the titration vessel the working medium is added. It must contain at least 25–50% methanol, since the alcohol is not only a solvent but takes also part in the reaction mentioned above. The other 50–75% can be a large variety of solubilizers as formamide, halogenated solvents or long-chained alcohols. The used quantity

depends on the nature of the solubilizer. The working medium is titrated to dryness (pre-titration) in the first step, then the sample is added and the water content is determined. The one-component titration has the advantage that the working medium in the titration vessel can be varied according to the requirements of the sample.

In the volumetric two-component titration the buret is filled with the "Titrant". In the titration vessel the Karl Fischer Solvent is added. The solvent in the vessel is titrated to dryness, then the sample is added and the water content is determined. Two-component titrations have a rapid titration rate and highly accurate results.

For both types of volumetric Karl Fischer titration, the titration with a one-component reagent and a two-component reagent, respectively, a titer determination is necessary.

The Karl Fischer anolyte consists of iodide as active ingredient. The iodine necessary for the Karl Fischer reaction is generated by anodic oxidation of iodide to iodine. The iodine reacts at once with the water according to Eq. 1. The amount of water titrated is proportional to the total current consumption and can be calculated using Faraday's law. For this type of water determination two coulometric cell types are in use, a cell with diaphragm, consisting of an anodic and a cathodic compartment, and a cell without diaphragm, respectively. The so-called diaphragmless cell consists of one compartment, the anodic compartment only. For a coulometric titration the anodic Karl Fischer reagent is filled in the large anodic compartment of the coulometric cell. The cell with diaphragm requires the catholyte, which has to be filled into the small cathodic compartment. The compartment is separated from the anodic compartment with a ceramic diaphragm. In the diapragmless cell, a special cathodic reagent is not necessary. In the first step the reagent is automatically titrated to dryness. Then the sample is added and the water content is determined. Since the coulometric titration is much more sensitive than the volumetric titration the sample has to be added using a syringe. A rubber seal is pricked by the tip of the syringe. Using this procedure the sample can be added without transfer of air humidity into the cell. In coulometric titration a titer determination is not necessary since the current is measured directly.

A third form of Karl Fischer titration is the non-direct titration using Karl Fischer oven technique. There are samples, which should not have direct contact with a Karl Fischer reagent. In some cases, they react with the ingredients of the reagent, sometimes they are not soluble in the typical Karl Fischer solubilizers. Those samples can be analyzed using the Karl Fischer oven. Depending on type of oven, the sample is weighted in a vial or small bottle, then it is heated at a suitable temperature until the water is evaporated and transferred by a carrier gas into the volumetric or coulometric Karl Fischer cell. There the water is determined according to the standard techniques.

## 7 THE KARL FISCHER TITRATION IN THE NATIONAL PHARMACOPOEIAS

The national pharmacopoeias describe the Karl Fischer titration as a method for water determination. Traditionally a one-component reagent is preferred in the

pharmaceutical quality control. But in the latest editions, other modern techniques have also found their way into the pharmacopoeias. Here we will give a short overview of the recommendations.

## 7.1 USP (United States Pharmacopoeia), 921 Water Determination (5)

It describes a titrimetric, gravimetric and destillation method for water determination. The titrimetric Karl Fischer titration is divided into direct volumetric, volumetric residue and coulometric titration. A composition instruction for a pyridine-containing reagent is given but the reagents can be purchased as well. Bases and solvents in the commercially available reagents can be varied in a broad rage so that pyridine and methanol are not necessary. A detailed standardization procedure is given which prescribes the use of sodium tartrate dihydrate as water reference substance. For the coulometric Karl Fischer titration commercially available apparatus and reagents are recommended and not specified in detail.

## 7.2 European Pharmacopoeia (6)

***7.2.1 Water: Semi-Micro Determination*** First in the European Pharmacopoeia a volumetric titration method is prescribed. Direct titration and residue titration is possible. The reagent (so-called "titrant") is not given in detail, each commercially available reagent is possible which fulfils the requirements of the standardization procedure. Water or a certified reference material must be used for standardization, the titer of the reagent must be not less than 80% of that is indicated by the supplier. The accuracy of the determination with the chosen titrant must be verified for each substance to be examined. First time a detailed suitability test is prescribed in the monograph 5.7 (2007).

***7.2.2 Water: Micro Determination*** On this page the coulometric Karl Fischer titration is listed. The apparatus consists of a cell with diaphragm, the reagent composition is not given in detail, and commercially available reagents are indicated to be suitable.

## 7.3 Japanese Pharmacopoeia, 2.48 Water Determination (Karl Fischer Method) (7)

***7.3.1 Volumetric Titration*** In the Japanese Pharmacopoeia detailed preparation methods for three various "Karl Fischer Titrating Solutions" (TS) are prescribed. Similar reagents with the mentioned ingredients can be purchased by reagent suppliers. Also a standardization procedure for the reagent is given which uses a methanol–water solution as standardization reagent. The text gives detailed procedures for direct titration, residue titration, direct extraction of insoluble samples and, at least gas extraction using the Karl Fischer oven technique.

***7.3.2 Coulometric Titration*** For coulometric Karl Fischer titration the use of a cell with diaphragm is recommended. The preparation of three various anolyte and catholyte solutions is given in detail. Similar solutions are offered by common reagent suppliers so the work of preparation of own reagents can be saved. The technique of direct coulometric titration is prescribed, for insoluble samples the Karl Fischer oven technique is recommended.

## 8 PRACTICE OF THE KARL FISCHER TITRATION

In this chapter, standard titration techniques and their variations for particular samples will be shown. For each technique a typical example out of the field of pharmaceutical chemistry is given.

### 8.1 Direct Titration with a One-Component Reagent: Example Ipatropium Bromide

Thirty milliliter of dry methanol or another appropriate solvent are placed in the titration vessel and titrated to dryness with Karl Fischer reagent Composite 5. Around 500 mg of the sample, exactly weighed by difference, is weighed in and titrated with Composite 5.

The analysis can also be done with the two component reagent.

The same procedure is usable for Cefalexine, Polysorbate 80, Povidone, Oxytetracycline hydrochloride, Sodium acetate trihydrate, Atropinsulfate hydrate, Dexpanthenol, Promethazine hydrochloride, Salbutamol hemisulfate, or Poloxamere.

### 8.2 Direct Titration with a One-Component Reagent in a Buffered Working Medium: Example Hexetidine

Thirty milliliter of methanol and 5 g of salicylic acid are placed in the titration vessel and titrated to dryness with Composite 5. Around 500 mg of the sample, exactly weighed by difference, is weighed in and titrated.

The analysis cannot be done with a two-component reagent.

The same procedure is usable for Penicilline, Dobutamine hydrochloride, or Calcium nitrate tetrahydrate.

### 8.3 Direct Titration Using a Solubilizer for Non-Polar Samples: Example Sorbitan Monostearate

Thirty milliliter of a mixture of methanol and chloroform are placed in the titration vessel and titrated to dryness with Composite 5. A sample of 1 g is weighed in exactly using differential weighing. It dissolves quickly and the water content is titrated with Composite 5.

If chloroform should be avoided for environmental reasons the working medium could also made of a mixture of methanol and hexanol or of an ethanolic working medium. In both cases the titration vessel must be heated to dissolve the sample

completely. The same procedure can be used for Peanut oil, Almond oil, Cellulose acetate phtalate, Fluticasone proprionate and Hexane.

## 8.4 Direct Titration Using a Solubilizer for Hydrophilic Samples: Example l-Leucovorin

The sample does not dissolve in usual Karl Fischer working media. A mixture of methanol and formamide and the addition of salicylic acid give appropriate results.

The titration vessel is filled with 20 mL methanol, 20 mL formamide and 7 g salicylic acid and titrated to dryness with Composite 5.

Approximately 0.1 g sample is accurately weighed in using the "weighing-by-difference" technique and titrated with Composite 5. The titration vessel can be heated to achieve acceleration. The same procedure can be used for Caciumfolinate and Cloracilline sodium salt hydrate.

## 8.5 Direct Titration Using Karl Fischer Solvent in the Titration Vessel: Example Salbutamol Hemisulfate

Salbutamol hemisulfate does not dissolve in methanol. When the more polar Karl Fischer Solvent (containing sulfur dioxide and a base in methanol, see Chapter 5) is used, the substance dissolves rapidly.

Thirty milliliter Karl Fischer Solvent are placed in the titration vessel and titrated to dryness with Titrant 5 or Composite 5. Approximately 0.3 g sample, determined by differential weighing, is precisely weighed in and the water content is titrated with Titrant or Composite.

A titration in methanol or ethanolic working media is also possible, the sample does not dissolve completely but the water is extracted.

## 8.6 Direct Titration of Acids Using a Buffered Working Medium: Example Folic Acid

Folic acid does not dissolve in the usual Karl Fischer working media. The titration times are very long. When a mixture of sulfur dioxide and imidazol in methanol is used in the titration vessel, the extraction of the water is highly improved.

Ten milliliter methanol and 20 mL Karl Fischer Buffer Acid are filled into the titration vessel and titrated to dryness with Composite 5. Approximately 0.2 g sample, exactly weighed by difference, is added into the titration vessel. The water content is determined with Composite 5.

The same procedure can be used for adenosine triphosphate.

## 8.7 Direct Titration with Suppressed Side-Reaction: Example Penicillin

Pure penicillin does not undergo a side-reaction with Karl Fischer reagents. But in respect to its production process free penicillin acid is found as impurity in many

commercial penicillins. The penicillin acid reacts with iodine and therefore must be neutralized.

Thirty milliliter methanol and 5 g of salicylic acid are placed in the titration vessel and titrated to dryness with Composite 5. Then approximately 0.5 g sample is weighed in accurately by back-weighing and its water content titrated with Composite 5. The same procedure can be used for Beserazid hydrochloride and Trolamine.

## 8.8 Direct Titration of Ketones and Aldehydes: Example Acetone

As mentioned in Chapter 3 ketones and aldehydes need particular reagents since they tend to undergo side-reactions with Karl Fischer reagents. Methanol should be avoided. Suitable solvents for the Karl Fischer titration in ketones are chloroethanol (caution: highly toxic!), less toxic are mixtures of chloroform and methoxypropanol.

Thirty milliliter Karl Fischer Medium K is filled in the titration vessel and titrated to dryness with a special Karl Fischer Composite For Ketones. 5 mL acetone is added using a glass syringe and weighed be difference. The water content is titrated with Composite 5 For Ketones. If more than one sample should be investigated, the working medium has to be replaced after 10 mL acetone. The same procedure can be used for Methyl-iso-butylketone.

## 8.9 Titration in a Heated Titration Vessel: Example D-(+)Glucose (Dextrose)

Thirty milliliter dry methanol are placed in the titration vessel, heated to 50°C and titrated to dryness with Karl Fischer reagent Composite 5. Approximately 500 mg of the sample is then precisely weighed in by difference. It should dissolve quickly in the heated working medium. The water content is titrated with the titrating reagent.

The titration can also be done at room temperature. In this case the working medium has to be replaced by a 1:1 mixture of dry formamide and methanol. Further examples to be used with this technique are Lactose Monohydrate, Fructose or other mono saccharides.

Samples as Corn starch, Glycerol dibehenate, or Sorbitan monostearate require definitive the titration at 50°C.

## 8.10 Titration in a Cooled Titration Vessel

This variation is also possible but, according to our knowledge, not required in the various pharmacopoeias. Just for the sake of completeness of Karl Fischer techniques it should be mentioned. The titration vessel of a volumetric Karl Fischer titrator can be cooled down to 0°C or, in some particular cases to −40°C. Then the titration should be performed with a two-component-reagent. This technique is used for the water determination in organic peroxides as peresters and percarbonates and requires dedicated end-point parameters.

## 8.11 Indirect Titration Using the Karl Fischer Oven

The use of the Karl Fischer oven is an elegant way to avoid the contact of the sample and the Karl Fischer reagents. It is recommended for insoluble and reactive substances. A stream of dried air is conducted over the sample, which is heated to the necessary temperature. The water evaporates and is conducted into the Karl Fischer cell. There, the titration takes place. Usually, the Karl Fischer oven is used in connection with a Karl Fischer coulometer. An additional benefit of this technique is the possibility for automation.

We do not describe a method for a special product since for each product a suitable temperature has to be found. If a lot of identical samples has to be analyzed the Karl Fischer oven can be a reliable alternative to manual Karl Fischer titration.

## 8.12 External Extraction in Dry Methanol

Another unusual but advantageous way of Karl Fischer titration is the external extraction in dry methanol. The sample is added in a vial which contains a defined amount of dry methanol, for example 10 mL. The vial is closed with a septum cap. After a suitable extraction time (overnight has proved itself), an aliquot is taken with a microliter glass syringe and added into the titration cell. There the water content is determined without problems of solubility or side-reactions. It is important to take the blank value into consideration, since the vial, the methanol and the syringe bring a minimal water amount into the analysis. It must be also considered that 1 mL dry methanol can extract maximal 1 mg water. In the last 20 years Herold (8) has made comprehensive investigations on this technique. He developed mutual standard procedures for a wide range of unrelated products as herbal drugs, gelatine capsules, organic solvents, powders and tablets.

## 8.13 The External Extraction Using Dried Karl-Fischer Anolyte: Example Lyophilized Material

Pharmaceutical preparations for injection are often supplied as lyophilized substrate in a vial. These substances are highly hygroscopic so the vial should not be opened for sample preparation. The water content is typically in the range about 100 μg per vial. For the determination of these small water contents the coulometric titration and the extraction of the water with dried Karl Fischer anolyte is recommended.

The coulometric titration cell is filled and dried as prescribed in Chapter 6. A syringe with a long needle is used the take approximately 5 mL anolyte out of the cell and re-inject it back at once. This procedure is repeated several times until the syringe is dry. Then 5 mL anolyte was taken again and this amount is injected into the vial with the lyophilized material. The substance is dissolved by shaking. Then the solution is drawn into the syringe again and injected into the anodic compartment of the coulometric cell. The water content is determined as usual. A blank of the whole

method can be investigated when the whole procedure is carried out with an empty vial.

In rare cases lyophilisates have a water content of 1% and more. For these materials the vials can be opened and the extraction with anolyte is not necessary.

## 9 TITRATION CURVES

In this chapter, we want to show several typical titration curves of Karl Fischer titrations. A variety of Karl Fischer titrators offer the possibility to print out the titration curve of the actual titration. It can be used to check the stability of the end point, the occurrence of a side-reaction or an extraction problem.

The curve above shows the reagent consumption versus titration time (Figure 2). A quick Karl Fischer titration of approximately 3 minutes can be seen. In the beginning of the titration the reagent is added fast, nearer to the end point the reagent dosage becomes slower until it stops.

***FIGURE 2*** *Karl Fischer titration without problems: glycerol in methanol by volumetric titration.*

In Fig. 3a the typical side-reaction of ketones in methanol can be seen. The acetone forms an acetal with methanol and water is released during this slow reaction. The water is titrated and no end point can be found. After 15 minutes the titration is stopped manually. In Fig. 3b the titration takes place in Medium K, the methanol-free working medium for Karl Fischer titration. The side reaction is suppressed, not water is formed and a stable end point is achieved after 2 minutes.

***FIGURE 3*** *Aceton in (a) methanol and (b) Medium K.*

In Fig. 4 the advantage of a solubilizer is shown. Curve 2 shows the titration behavior in pure methanol as working medium. The salt is dissolved incompletely and therefore the water is released slowly. The titration does not find an end point and is manually stopped after 15 minutes. Curve 1 shows the titration in a mixture of formamide and methanol. This solution dissolves the sample quickly and a stable end point is found after 3 minutes.

***FIGURE 4*** *Potassium citrate in methanol (2) and in methanol/formamide (1).*

## 10 QUALITY ASSURANCE

Karl Fischer titrators are quality relevant instruments in respect to ISO 9000 and GLP and therefore have to fulfill whose requirements. In practice three main issues have to be considered for these guidelines:

- Working instructions for water determinations and for instrument control must be defined in writing.
- Results must be documented to assure the retrieval of the analytical data at a later time.
- The analytical instrumentation must be inspected periodically to assure delivery of exact and precise measurement.

Validating analytical instruments is necessary and ensures proper functioning of the titrators. The documentation of such tests suggests that the results obtained from the inspected unit are correct. We recommend regular check of the whole system instrument AND reagents with defined commercially available water standards. These standards are measured against NIST SRM 2890, easy to apply and include a certificate of analysis showing the individual water content and its uncertainty.

## 1 INTRODUCTION

The EDTA titration is based on the stoichiometric formation of water-soluble metal-EDTA complex to determine the concentration of the metal ion in aqueous solution. "EDTA" is the abbreviation of "ethylenediaminetetraacetic acid" or its anion, "ethylenediaminetetraacetate." Owing to its chemical structure, EDTA forms stable, water-soluble, 1:1 complexes with most polyvalent metal ions. This distinctive property sets the basis of the EDTA titration, and is also the reason that EDTA titrations are categorized as complexation titrations. In fact, a vast majority of complexation titrations employ EDTA as the complexing agent, and are thus EDTA titrations.

Fundamental studies on EDTA and related compounds can be traced back to 1930s. Schwarzenbach and his coworkers have studied the titrations with EDTA since the mid-1940s. In 1948, they reported that the endpoint of an EDTA titration might be detected by metal-sensitive indicators such as Murexide and Eriochrome Black T. Since then, the application of EDTA in titrations has been widely studied. A number of authors have presented the topic in full-length and well-organized styles [1–4].

Nowadays, with the development of analytical technology, various techniques are available for the analysis of metal ions. In addition to the conventional methods, advanced instrumental techniques such as atomic absorption spectroscopy (AAS),

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing,*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

inductively coupled plasma mass spectrometry (ICP-MS), and inductively coupled plasma atomic emission spectroscopy (ICP-AES) have proved great advantages for metal analysis. However, the EDTA titration is still widely used for quantitative analysis because of its unique advantages such as ease of operation, low cost of equipment, and minimal maintanence requirement. This is because the EDTA titration is simple to operate, can produce accurate results for samples with different complexities, and does not require costly instrumentation and specialized personnel. Moreover, with well-designed masking/de-masking schemes, EDTA titrations are capable for sequential analysis of multiple metal ions in a single sample without separation and extraction operations.

In this chapter, the EDTA titration is discussed from basic principles, titration curves, endpoint detection, titration types, and practical considerations. Some practical examples on the determination of various ions are also given at the end of the chapter.

## 2 IONIZATION OF EDTA

The structural formula of ethylenediaminetetraacetic acid (molecular weight 292.25) can be written as:

It can be seen that EDTA is a quadrivalent acid. The four hydrogen ions on the carboxyl groups can be ionized successively with the increase of pH. Schwarzenbach et al. have measured the ionization constants at the ionic strength of 0.1 M KCl and at 20°C. Based on their data [5], the ionization of the four hydrogen ions on EDTA can be expressed as:

$$H_4Y \rightleftharpoons H^+ + H_3Y^- \qquad K_1 = \frac{[H^+][H_3Y^-]}{[H_4Y]} = 10^{-2.0} \tag{1}$$

$$H_3Y^- \rightleftharpoons H^+ + H_2Y^{2-} \qquad K_2 = \frac{[H^+][H_2Y^{2-}]}{[H_3Y^-]} = 10^{-2.67} \tag{2}$$

$$H_2Y^{2-} \rightleftharpoons H^+ + HY^{3-} \qquad K_3 = \frac{[H^+][HY^{3-}]}{[H_2Y^-]} = 10^{-6.16} \tag{3}$$

$$HY^{3-} \rightleftharpoons H^+ + Y^{4-} \qquad K_4 = \frac{[H^+][Y^{4-}]}{[HY^{3-}]} = 10^{-10.26} \tag{4}$$

where $H_4Y$, $H_3Y^-$, $H_2Y^{2-}$, $HY^{3-}$, and $Y^{4-}$ refer to the molecular and ionized species of EDTA at different ionization levels, respectively. $K_1$, $K_2$, $K_3$, and $K_4$ are the corresponding ionization constants. It can be seen from the constants that EDTA is a mid-strong acid and the first two hydrogen ions are much easier to ionize than the rest of the hydrogen ions.

The mole fraction of each of the EDTA species is a function of pH if the ionic strength and the temperature are constant. From Eqs. 1–4, the mole fractions of the EDTA species can be obtained:

$$a_0 = \frac{[H_4Y]}{C_{EDTA}} = \frac{[H^+]^4}{[H^+]^4 + K_1[H^+]^3 + K_1K_2[H^+]^2 + K_1K_2K_3[H^+] + K_1K_2K_3K_4} \quad (5)$$

$$a_1 = \frac{[H_3Y^-]}{C_{EDTA}} = \frac{K_1[H^+]^3}{[H^+]^4 + K_1[H^+]^3 + K_1K_2[H^+]^2 + K_1K_2K_3[H^+] + K_1K_2K_3K_4} \quad (6)$$

$$a_2 = \frac{[H_2Y^{2-}]}{C_{EDTA}} = \frac{K_1K_2[H^+]^2}{[H^+]^4 + K_1[H^+]^3 + K_1K_2[H^+]^2 + K_1K_2K_3[H^+] + K_1K_2K_3K_4} \quad (7)$$

$$a_3 = \frac{[HY^{3-}]}{C_{EDTA}} = \frac{K_1K_2K_3[H^+]}{[H^+]^4 + K_1[H^+]^3 + K_1K_2[H^+]^2 + K_1K_2K_3[H^+] + K_1K_2K_3K_4} \quad (8)$$

$$a_4 = \frac{[Y^{4-}]}{C_{EDTA}} = \frac{K_1K_2K_3K_4}{[H^+]^4 + K_1[H^+]^3 + K_1K_2[H^+]^2 + K_1K_2K_3[H^+] + K_1K_2K_3K_4} \quad (9)$$

$$C_{EDTA} = [H_4Y] + [H_3Y^-] + [H_2Y^{2-}] + [HY^{3-}] + [Y^{4-}] \quad (10)$$

where $\alpha_0$, $\alpha_1$, $\alpha_2$, $\alpha_3$, and $\alpha_4$ are the mole fractions for $H_4Y$, $H_3Y^-$, $H_2Y^{2-}$, $HY^{3-}$, and $Y^{4-}$, respectively. $C_{EDTA}$ refers to the sum of the concentrations of the molecular EDTA and its four ionic species. Figure 1 shows the mole fractions of these EDTA species as a function of pH. It can be seen that $H_4Y$ and $H_3Y^-$ are the major species when pH < 3. $H_2Y^{2-}$ and $HY^{3-}$ mainly exist as pH ranges between 3 and 10, in which

***FIGURE 1*** *The ionization degree of EDTA as a function of pH.*

most EDTA titrations are carried out. $Y^{4-}$ exists only in strong alkaline medium (pH > 10). Only a few of EDTA titrations are carried out in strong alkaline medium. This is because most of the metal ions of interest hydrolyze when pH > 9. Therefore, $H_2Y^{2-}$ and $HY^{3-}$ are the ionic species that exist and react with the metal ions in most EDTA titrations.

## 3 BASIC EDTA AGENTS FOR TITRATION

*MolecularEDTA ($H_4Y$):* The molecular EDTA is a free acid, which is a white, odorless, anhydrous powder. It is nearly insoluble in water (0.02 g per 100 g water at 22°C). The acid can be freed of absorbed water at 130–145°C for several hours.

*Sodium Dihydrogen Salt ($Na_2H_2Y_2{\cdot}2H_2O$):* The dihydrate of sodium dihydrogen salt is fairly soluble in water (11.1 g per 100 g at 21°C). This salt can slowly absorb up to 0.3% of moisture in the air. The moisture can be removed by drying at 80°C for at least 24 hours, so that the composition is brought to exactly that of the dehydrate formula.

## 4 FORMATION OF METAL-EDTA COMPLEXES

The complexation between EDTA and metal ions is characterized by three points: (*i*) EDTA forms stable complexes with most metal ions; (*ii*) EDTA complexes with metal ions at a ratio of 1:1 regardless of the charge of the metal ion; and (*iii*) all the hydrogen ions on the EDTA carboxyl groups are released once the metal-EDTA complex is formed.

The stability constant ($K_{MY}$) of the metal-EDTA complex is defined as:

$$M^{n+} + Y^{4-} \rightleftharpoons MY^{n-4} \tag{11}$$

$$K_{MY} = \frac{[MY^{n-4}]}{[M^{n+}][Y^{-4}]} \tag{12}$$

where $M^{n+}$ refers to the "free" metal ion with positive charge n. $MY^{n-4}$ refers to the metal-EDTA complex. Table 1 lists the stability constants for common metal ions at certain ionic strengths and temperatures. It can be seen from the table that most of the metals including alkaline earths, transition metals, rare earths, and actinides have a stability constant larger than $10^8$, which is large enough for the metal ion to be determined by the EDTA titration. Only a few metals, such as the alkali metals, Ba, Ra, Ag, and Tl(I), have a stability constant less than $10^8$. These metal ions form weak metal-EDTA complexes and are not suitable to be directly determined by EDTA titration, but can be measured by indirect EDTA titration methods.

Because $H_2Y^{2-}$ and $HY^{3-}$ are the major EDTA species in most titrations, the formation of the metal-EDTA complex in the EDTA titration may be expressed as:

$$M^{n+} + H_2Y^{2-} \rightleftharpoons MY^{n-4} + 2H^+ \quad \text{(pH 3–6)} \tag{13}$$

$$M^{n+} + HY^{3-} \rightleftharpoons MY^{n-4} + H^+ \quad \text{(pH 6–10)} \tag{14}$$

**TABLE 1 Stability Constants of Metal-EDTA Complexes* [6]**

| Metal Ion | Log $K_{MY}$ | Metal Ion | Log $K_{MY}$ | Metal Ion | Log $K_{MY}$ |
|---|---|---|---|---|---|
| Co(III) | 41.4 | Er(III) | 18.89 | $VO_2$(I) | 15.5 |
| Tl(III) | 35.3 | Cu(II) | 18.78 | La(III) | 15.36 |

| Tm(III) | 19.32 | Ce(III) | 15.93 | | |

* Most of the stability constants are obtained at 25°C and ionic strength 0.1 M except:
[a] 20°C and ionic strength 0.1 M,
[b] 20°C and ionic strength 1 M.

Notice that all carboxyl hydrogen ions on the EDTA are released once the complex is formed.

The fact that EDTA forms $My^{n-4}$ complex with metal ions can be explained from its chemical structure. EDTA is an aminopolycarboxylic acid with six ligand groups (i.e., four single-bonded oxygen atoms in the ionized carboxyl groups and two nitrogen atoms in the amino groups). As most metal ions show a coordination number of 6 or 8 in the formation of complexes, all the six ligand atoms on EDTA will take part in the complexation. Note that EDTA has a structure with any of the two neighbored ligand atoms being separated by two carbon atoms. This leads to a five-numbered ring structure when the two neighbored ligand atoms chelate with the metal ion. Thus, a metal-EDTA complex can form as many as 5 five-numbered rings if all the four carboxyl hydrogen ions are ionized. According to coordination chemistry, a five-numbered ring structure is the most stable chelate structure. Therefore, when complexing with a metal ion, EDTA will release all the hydrogen ions on the carboxyl groups and form 1:1 metal-EDTA complex with five chelate rings, so that a structure with high stability is achieved (Fig. 2).

## 5 CONDITIONAL STABILITY CONSTANT

In the EDTA titration, the stability constant of the metal-EDTA complex is mainly affected by two important factors: (*i*) the medium pH and (*ii*) the concentration of the auxiliary complexing agent.

***FIGURE 2*** *The structure of a metal-EDTA complex.*

Metal ions with different stability constants can be titrated by adjusting these two factors. The conditional stability constant of the metal-EDTA complex is the stability constant, considering the effects of these two factors, which are quantitatively discussed in the following.

***pH Effect:*** The stability of the metal-EDTA complex is very sensitive to the medium pH. At low pH, the ionic EDTA species tend to combine with hydrogen ion. The complexing equilibrium in Eq. 13 or 14 shifts toward the left. The metal-EDTA complex becomes less stable. On the other hand, at high pH, more hydrogen ions ionize from the EDTA. The complexing equilibrium in Eq. 13 or 14 will shift toward the right. The metal-EDTA complex becomes more stable. However, as the metal ion hydrolyzes to form various hydroxyl species or precipitates in alkaline condition, complicated species other than 1:1 metal-EDTA complex will be produced when pH is too high, which is generally avoided in the EDTA titration.

Due to the strong dependence on pH, the EDTA titration is normally carried out in a buffered solution where the medium pH is controlled at a constant predetermined value for the titration. Under such a condition, the stability of a metal-EDTA complex can be readily evaluated.

Combining Eqs. 9 and 12, a conditional stability constant ($K_{\text{MY-pH}}$) can be obtained to evaluate the pH effect on the metal-EDTA complexation:

$$K_{\text{MY-pH}} = \frac{[\text{MY}^{n-4}]}{[\text{M}^{n+}]C_{\text{EDTA}}} = \frac{[\text{MY}^{n-4}]}{[\text{M}^{n+}]([\text{Y}^{-4}]/\alpha_4)} = K_{\text{MY}}\alpha_4 \tag{15}$$

where $C_{EDTA}$ refers to the sum of the concentrations of all the five EDTA species ($H_4Y$, $H_3Y^-$, $H_2Y^{2-}$, $HY^{3-}$, and $Y^{4-}$). From Eq. 15, it can be seen that $K_{MY\text{-}pH}$ increases with the increase of pH and decreases with the decrease of pH. Note that Eq. 15 only considers the effect of pH on the ionization of EDTA; the hydrolysis of the metal ion is not included. This is because the hydrolysis of metal ion will significantly change the mechanism of the metal-EDTA reaction and complicate the basic complex reaction on which the EDTA titration is carried out. Practically, the medium pH is controlled in the range where the hydrolysis of metal ion does not affect the formation of the metal-EDTA complex. Under the circumstances that the EDTA titration has to be conducted in the pH range where the metal-ion hydrolysis is significant, an auxiliary complexing agent is usually added. The effect of the auxiliary complexing agent on the EDTA titration is discussed in the following section.

***The Effect of the Auxiliary Complexing Agent:*** In many EDTA titrations, an auxiliary complexing agent is added to prevent the hydrolysis of metal ion. Normally, a monodentate ligand is used as the auxiliary complexing agent, which complexes with the metal ion and changes the stability of the metal-EDTA complex. The effect of the auxiliary agent can be readily evaluated because it is often added in excess amount and its concentration is considered constant throughout the EDTA titration. Suppose the auxiliary complexing agent, L, combines with the metal ion by forming a series of complex species with the corresponding stability constants ($K_{ML1}$, $K_{ML2}$, $K_{ML3}$, $K_{ML4}$, ...):

$$M^{n+} + L^{m-} \rightleftharpoons ML^{n-m} \qquad K_{ML1} = \frac{[ML^{n-m}]}{[M^{n+}][L^{m-}]} \tag{16}$$

$$ML^{n-m} + L^{m-} \rightleftharpoons ML_2^{n-2m} \qquad K_{ML2} = \frac{[ML_2^{n-2m}]}{[ML^{n-m}][L^{m-}]} \tag{17}$$

$$ML_2^{n-2m} + L^{m-} \rightleftharpoons ML_3^{n-3m} \qquad K_{ML3} = \frac{[ML_3^{n-3m}]}{[ML_2^{n-2m}][L^{m-}]} \tag{18}$$

$$\cdots \quad \cdots \quad \cdots \quad \cdots \quad \cdots \quad \cdots$$

$$\beta_{ML} = \frac{[M^{n+}]}{C_M} = \frac{1}{1 + K_{ML1}[L] + K_{ML1}K_{ML2}[L]^2 + K_{ML1}K_{ML2}K_{ML3}[L]^3 + \cdots} \tag{19}$$

where $m$ is the charge of the auxiliary complexing agent. $C_M$ is the sum of the concentrations of the metal ion and its complex species with L. $\beta_{ML}$ is the mole fraction of the metal ion with respect to $C_M$. It is noticed that the protonation of the auxiliary complexing agent is not considered here. This approximation is reasonable because the auxiliary complexing agent is normally used at high pH to prevent the metal hydrolysis. The protonation of the auxiliary complexing agent is negligible compared with its metal-complexation reaction.

Therefore, the conditional stability constant of the metal-EDTA complex considering the effect of the complexation with the auxiliary agent can be written as:

$$K_{\text{MY-L}} = \frac{[\text{MY}^{n-4}]}{C_{\text{M}}[\text{Y}^{-4}]} = \frac{[\text{MY}^{n-4}]}{([\text{M}^{n+}]/\beta_{\text{ML}})[\text{Y}^{-4}]} = K_{\text{MY}}\beta_{\text{ML}} \tag{20}$$

Combining Eqs. 15 and 20 gives a conditional stability constant ($K'_{\text{MY}}$) considering the effects of both EDTA ionization and the complexation with the auxiliary agent:

$$K'_{\text{MY}} = \frac{[\text{MY}^{n-4}]}{C_{\text{M}}C_{\text{EDTA}}} = \frac{[\text{MY}^{n-4}]}{([\text{M}^{n+}]/\beta_{\text{ML}})([\text{Y}^{-4}]/\alpha_4)} = K_{\text{MY}}\alpha_4\beta_{\text{ML}} \tag{21}$$

$$\log K'_{\text{MY}} = \log K_{\text{MY}} + \log a_4 + \log \beta_{\text{ML}} \tag{22}$$

## 6 TITRATION CURVES

In analogy to the acid-base titration, the EDTA titration curve can be drawn by plotting pM ($= -\log\,[\text{M}^{n+}]$) versus the volume of the EDTA titrant or the percent of the stoichiometric amount of EDTA added. The titration curve is not only for understanding the titration process, but also for evaluating the key factors in developing new EDTA titrations.

Suppose the sample solution to be titrated has a volume of $V_0$ and a metal concentration of $C^0_{\text{M}}$. The EDTA titrant has a concentration of $C^0_{\text{Y}}$. If the volume of the EDTA titrant added at any point of the titration is $V_{\text{t}}$, then the percent of the stoichiometric amount of EDTA added can be expressed as $\phi = C^0_{\text{Y}}V_{\text{t}}/C^0_{\text{M}}V_0$. The titration curve can thus be obtained by plotting pM versus $\phi$.

The pH buffer and auxiliary complexing agent in a titration are normally in excess amount. So Eq. 21 can be directly used for the calculation of pM at any given point of titration because both $\alpha_4$ and $\beta_{\text{ML}}$ basically remain constant throughout the titration process. Combining Eqs. 9,19, and 21, a titration curve can be calculated in three steps:

1. *Before the equivalence point* ($\phi < 1$):

$$\text{pM} = \log\left[\frac{1+\phi\cdot\gamma}{C^0_{\text{M}}\beta_{\text{ML}}(1-\phi)}\right] \tag{23}$$

where $\gamma = C^0_{\text{Y}}/C^0_{\text{M}}$.

2. *At the equivalence point* ($\phi = 1$):

$$\mathrm{pM} = \frac{1}{2}\log\left[\frac{\alpha_4 K_{\mathrm{MY}}(1+\phi\cdot\gamma)}{C_{\mathrm{M}}^0\beta_{\mathrm{ML}}}\right] \tag{24}$$

3. *After the equivalence point* ($\phi > 1$):

$$\mathrm{pM} = \log[\alpha_4 K_{\mathrm{MY}}(\phi - 1)] \tag{25}$$

Figure 3 shows a group of titration curves with different stability constants ($K_{\mathrm{MY}}$). It can be seen that the titration curves have an "S" shape, with the inflexion point at the equivalence point of the curve. Among all the factors that affect the shape of the titration curve, the stability constant of the metal-EDTA complex is the most important. As shown in Fig. 3, the larger the $K_{\mathrm{MY}}$ value, the greater the pM change at the equivalence point. It is also noticed that $K_{\mathrm{MY}}$ does not affect the titration curve before the equivalence point. But as $K_{\mathrm{MY}}$ increases, the titration curve after the equivalence point is shifted up, and the pM change at the equivalence point is increased consequently. This can be understood in Eqs. 23–25, where $K_{\mathrm{MY}}$ appears only in the last two equations.

Since any titration is dependent on the quick pM change around the equivalence point, a titration curve with a sharp and large pM jump is crucial for the successful detection of the endpoint of the titration. Generally, it needs at least 2 units of pM change for a detection method to sense the endpoint. From Fig. 3, it can be seen that the titration curves with $K_{\mathrm{MY}} > 10^8$ have more than 2 units of pM change at the

***FIGURE 3*** *Titration curves with different stability constants ($K_{\mathrm{MY}}$).* Suppose the titrations are carried out at the condition: $C_{\mathrm{M}}^0 = 0.01\,\mathrm{M}$, $C_{\mathrm{Y}}^0/C_{\mathrm{M}}^0 = 1$, $\alpha_4$=1, and $[\mathrm{L}^{m-}] = 0\,\mathrm{M}$.

equivalence point. While the curves with $K_{MY} < 10^8$ have less than 2 units of pM change. This is the reason why it is difficult or impossible to conduct an EDTA titration with $K_{MY} < 10^8$. It can be seen from Table 1 that most of the metals have a stability constant greater than $10^8$ and thus can be determined by the EDTA titration.

***pH Effect on the Titration Curve:*** The medium pH can affect the conditional stability constant ($K'_{MY}$) of the metal-EDTA complex by changing the ionization of EDTA. From Eqs. 23–25, it can be seen that the titration curve before the equivalence point will not be affected by the medium pH. But the curve after the equivalence point will shift up with the increase of pH and shift down as the pH decreases. For this reason, a higher pH is generally favorable, provided that the hydrolysis of the metal ion does not affect the complexation reaction.

On the other hand, it is interesting to find out the minimum pH that causes a given $K'_{MY}$ decrease to $10^8$, which is just big enough to produce a 2-unit pM jump at the equivalence point of the titration curve. The minimum pH can be calculated with Eq. 15 by supposing $K'_{MY} = 10^8$. These values are important for the design of the EDTA titration under various conditions. Reilley and Schmid [7] have plotted the stability constant of the metal-EDTA complex versus the minimum pH for a number of metals. Similar diagram (Fig. 4) was drawn in this chapter with the data in Table 1. It can be seen from the figure that many metal ions can be titrated in the range between pH 3 and 10, while tetravalent and trivalent metal ions such as Zr (IV), Th(IV), Bi(III), Fe(III), In(III), and Sc(III) can be titrated in acidic media (pH < 3).

***Effect of the Auxiliary Complexing Agent on the Titration Curve:*** Under certain circumstances, the metal ion may hydrolyze at the pH where the EDTA titration is designed to conduct. The hydrolysis of metal ion produces hydroxides and precipitates that can significantly influence the EDTA titration by slowing down the EDTA complexation reaction or changing the complexation mechanism. Therefore, significant metal hydrolysis should always be avoided in an EDTA titration.

The addition of an auxiliary complexing agent can help prevent the metal hydrolysis. However, the stability of the metal-auxiliary agent complex should be much less than that of the metal-EDTA complex, so that the conditional stability constant ($K'_{MY}$) will not be less than $10^8$. In this way, as the titration proceeds, the auxiliary agent will be gradually replaced when the metal-EDTA complex is formed.

Unlike the pH effect, the addition of an auxiliary complexing agent will not change the titration curve after the equivalence point but move up the curve before the equivalence point. This can be understood from the equations of the titration curve. $\beta_L$ is contained in Eqs. 23 and 24, but not in Eq. 25.

Figure 5 shows the titration curves for Zn(II) at pH 10, with different concentrations of an auxiliary complexing agent, $NH_3$. The stepwise stability constants of Zn-$NH_3$ complexes [8] are $\log K_1 = 2.32$, $\log K_2 = 2.29$, $\log K_3 = 2.36$, and $\log K_4 = 2.39$, respectively. Together with the stability constant of Zn-EDTA complex ($\log K_{Zn\text{-}EDTA} = 16.5$ from Table 1) and the ionization constants of EDTA, the titration curves in Fig. 5 can be obtained. It can be seen that the curve before the equivalence point is shifted up with the increase of $[NH_3]$. The higher the $[NH_3]$, the smaller the pM jump

***FIGURE 4*** *The pH effect on the stability constants of the metal-EDTA complexes.*

at the equivalence point. Therefore, as long as that the metal hydrolysis is masked; the addition of the auxiliary complexing agent should be limited to the lowest concentration.

***The Concentration Effect:*** The concentration of the metal ion ($C_M^0$) may also affect the titration curve. It can be seen from Eqs. 23 and 24 that the titration curve before the equivalence point shifts up with the decrease of $C_M^0$. As a rule of thumb, every 10-fold decrease in $C_M^0$ will lead to the curve before the equivalence point shift up by 1 unit. Practically, $C_M^0$ is often adjusted in the range between 0.01 and 0.001 M for the EDTA titration. So the titration curve before the equivalence point is positioned between 2 and 4 on the pM-axis. If much lower $C_M^0$ has to be used, it is suggested that before the analysis the titration curve is plotted, the pM change at the equivalence point is checked, and the endpoint detection method is evaluated.

The concentration ratio of EDTA over the metal ion ($\gamma = C_Y^0/C_M^0$) affects the titration curve before the equivalence point. Figure 6 shows the titration curves for Ca with different $\gamma$ values. It can be seen that if the EDTA concentration is larger than that of the metal ion ($\gamma > 1$), the titration curve before the equivalence point is moved up,

***FIGURE 5*** *Titration curves for Zn(II) in the medium with different free [$NH_3$]. Suppose the titrations are carried out at the condition: $K'_{MY} = 10^{16.5}$, $C^0_M = 0.01$ M, pH = 10, and $C^0_Y/C^0_M = 1$.*

and the pM jump at the equivalence point is decreased. Furthermore, a larger analytical error will be introduced at the endpoint when the EDTA concentration is significantly larger than that of the metal ion. On the other hand, if the EDTA concentration is smaller than that of the metal ion ($\gamma < 1$), the curve before the equivalence point can shift down as much as 1 unit of pM. Further dilution of the EDTA concentration will not make any significant change to the titration curve, but will cause difficulty in the titration because it is impractical to accurately add a large

***FIGURE 6*** *Titration curves for $Ca^{2+}$ with different $\gamma$ ($= C^0_Y/C^0_M$). Suppose that $K'_{MY} = 5 \times 10^{10}$, $C^0_M = 0.01$ M, pH = 10, and $[L^{m-}] = 0$.*

volume of the titrant into the sample solution. Therefore, the proper concentration ratio ($\gamma$) for the titration should be in the range between 0.1 and 1.

## 7 ENDPOINT DETECTION METHODS

A successful titration depends on the accurate detection of the equivalence point, at which the amount of the titrant added is equivalent to the amount of the analyte presenting in the sample. The method used to detect the equivalence point is called "endpoint detection method." The endpoint is not necessarily to be exactly equal to the equivalence point. The precision related to the endpoint detection is affected not only by the endpoint method but also by the shape of the titration curve. Normally, an endpoint located within the pM jump at the equivalence point will produce a result with an error less than 1%, which is higher than the precision (5%) required for a titration analysis.

Many detection methods have been developed for the EDTA titration. These methods can be categorized into two groups: visual and instrumental detection methods.

A visual detection method usually employs a special agent (indicator) that shows the endpoint by a visual effect (change of color or production/disappearance of precipitation) that is discernable to the eye of the experimenter. Examples for visual indicators include metal-ion indicators, redox indicators, and precipitation indicators. Visual detection methods are normally easy to operate. Skillful experimenters can complete an EDTA titration with a visual detection within several minutes.

Instrumental detection methods include photometric, potentiometric, amperometric, conductometric, and thermometric methods. Instrumental methods are especially advantageous when combined into an automated titration system that is suitable for handling large numbers of samples with similar properties. Instrumental methods are also competitive in micro-titrations where very small amounts of sample are involved and it is difficult for human to discern a visual change. However, instrumental methods require more technical maintenance and are not as flexible as visual methods. It usually takes more time to complete a titration if an instrumental detection is used.

In the following two sections, we will discuss metal-ion indicators and potentiometric methods as examples of visual and instrumental methods.

***Metal-Ion Indicators:*** These visual indicators are organic dyestuffs characterized with functional groups that show different colors when complexing or not complexing with the metal ion. The functional groups of the metal-ion indicators are often composed of phenol and naphthol groups with many conjugated $\pi$-bonds. The delocalized electrons in these $\pi$-bonds are easy to be excited by visible lights so that different ionization states of these functional groups display various colors. A sharp color contrast between the dyestuff itself and the metal-dyestuff complex is essential for a dyestuff to be used as endpoint indicator in the EDTA titration.

When added as the metal-ion indicator, the dyestuff will complex with the metal ion and show a certain color. As the titration proceeds, the dyestuff is progressively replaced from the metal-dyestuff complex by the addition of EDTA. The liberated dyestuff displays a color different from that of the metal-dyestuff complex. The hue of the solution color changes slowly in the course of titration. At the endpoint, a color transition occurs when about half of the dyestuff is released from the metal-dyestuff complex. If it occurs within the pM jump of the titration curve, this color transition will be sharp enough for an experimenter to discern because the metal concentration changes most quickly in the pM change around the equivalence point. Consequently, the color transition provides a visual signal for the arrival of the endpoint.

Actually, the metal-ion indicators are often organic acids and have multiple ionic species with different colors. Taking a widely used metal-ion indicator, Eriochrome Black T, as an example, its ionic species at different pH can be shown as:

$$\underset{\text{red}}{H_2In^-} \xleftrightarrow{\text{pH } 5.3-7.3} \underset{\text{blue}}{HIn^{2-}} \xleftrightarrow{\text{pH } 10.5-12.5} \underset{\text{yellow/orange}}{In^{3-}} \tag{26}$$

It can be seen that Eriochrome Black T alone can show red, blue, and yellow/orange color in the ranges of pH $< 7$, pH 7–11, and pH $> 11$, respectively. As it has to give a sharp color change at the endpoint of titration, Eriochrome Black T can only work in certain pH range. The complexes of Eriochrome Black T with many metals (Ca, Mg, Cd, Zn, Ba, Mn, Hg, Pb, Cu, Al, Fe, Ti, Co, Ni, etc.) have a red color. This suggests that the indicator can only be used when pH is larger than 7. When pH $< 7$, the indicator itself is red, and no color transition will occur at the endpoint. Therefore, Eriochrome Black T is not suitable for the EDTA titration carried out in the media with pH $< 7$.

Another important condition for a dyestuff to be a metal-ion indicator is that the stability constant of the metal-dyestuff complex should match the titration so that the color transition (i.e., endpoint) occurs within the pM jump around the equivalence point of the titration. If the metal-dyestuff complex is not stable enough, the endpoint will occur before the pM jump. If the metal-dyestuff complex is too stable, a sluggish endpoint, a late endpoint, or no endpoint at all will be observed. Therefore, it is important to understand the relationship between the stability of the metal-dyestuff complex and the equivalence point of the titration.

Analogous to the EDTA complexation shown in Eq. 21, the conditional stability constant, $K'_{MIn}$, for the metal-dyestuff complex can be expressed as:

$$K'_{MIn} = \frac{[MIn]}{[M^{n+}]C_{In}} \tag{27}$$

where [MIn] refers to the concentration of the metal-indicator complex. The charge of the metal-dyestuff complex is omitted for simplicity. $C_{In}$ is the concentration of all the indicator species not combined with the metal ion. As to Eriochrome Black T, $C_{In}$ is equal to $[H_3In] + [H_2In^-] + [HIn^{2-}] + [In^{3-}]$ according to Eq. 26.

The relationship between $K'_{\mathrm{MIn}}$ and the color transition point can be evaluated by rearranging Eq. 27:

$$\log K'_{\mathrm{MIn}} = \mathrm{pM} + \log \frac{[\mathrm{MIn}]}{C_{\mathrm{In}}} \tag{28}$$

Suppose the color transition occurs at the point where half amount of the indicator is released from the metal-dyestuff complex; then Eq. 28 at the endpoint can be written as:

$$\log K'_{\mathrm{MIn}} = \mathrm{pM}, \quad \text{when}[\mathrm{MIn}] = C_{\mathrm{In}} \tag{29}$$

From Eq. 29, it is possible to tell whether a metal-ion indicator functions properly for a given EDTA titration. If log $K'_{\mathrm{MIn}}$ falls in the region of the pM jump at the equivalence point of the titration curve, the indicator is good for the titration. If log $K'_{\mathrm{MIn}}$ falls out of the region of the pM jump, the indicator is not suitable for the titration.

Flaschka [9] further studied the suitability of the metal-ion indicator to EDTA titration. According to his study, when common concentrations of the meal and the auxiliary complexing agent are used, a good metal-ion indicator should be the following: (*i*) The value of log $K'_{\mathrm{MIn}}$ must be 4 units less than that of log $K'_{\mathrm{MIn}}$ of the metal-EDTA complex; (*ii*) the value of log $K'_{\mathrm{MIn}}$ itself should be larger than 5; and (*iii*) the concentration ratio of the indicator to the metal ion should be less than $10^{-2}$.

It is noticed that similar to log $K'_{\mathrm{MIn}}$, log $K'_{\mathrm{MIn}}$ for the metal-dyestuff complex is also dependent on the medium pH because metal-ion indicators are usually organic acids. Therefore, the suitability of a metal indicator to a given EDTA titration is related to the medium pH of the titration. For example, the log $K'_{\mathrm{MIn}}$ of Eriochrome Black T complexes with Ca and Mg were found varying at different pH, as shown in Table 2. If a 0.01 M Ca sample solution is to be titrated under the condition: $[NH_4{}^+] = 0.1$ M and pH = 10, one can see from Fig. 7 that Eriochrome Black T is not a satisfactory indicator because log $K'_{\mathrm{CaIn}}$ (3.8) is small and falls out of the pM jump (4–8) of Ca titration curve. This leads to a vague color transition and early endpoint detection. A method called "replacement titration" is often used to overcome such a problem. As to Ca titration, several drops of Mg-EDTA are added in the sample solution before the titration. Because Ca-EDTA complex is more stable than Mg-EDTA complex, EDTA will complex with Ca before complexing with Mg. Therefore, it is Mg, not Ca, to show the endpoint with the dyestuff (Eriochrome Black T). Because log $K'_{\mathrm{MgIn}} = 5.4$ at pH 10, the color transition is within the pM jump of the Mg titration curve. A sharp color change from red to blue occurs to give the correct endpoint. Note that no titrant is consumed by Mg in this method because Mg is added as its EDTA complex.

**TABLE 2 The Conditional Stability Constants of Eriochrome Black T with Ca and Mg at Different pH**

| pH | 7 | 8 | 9 | 10 | 11 | 12 |
|---|---|---|---|---|---|---|
| Log $K'_{\mathrm{MgIn}}$ | 2.4 | 3.4 | 4.4 | 5.4 | 6.3 | 6.8 |
| Log $K'_{\mathrm{CaIn}}$ | 0.8 | 1.9 | 2.8 | 3.8 | 4.7 | 5.3 |

***FIGURE 7*** *The relationship between the metal-ion indicator and the endpoint. Sample solution: $[Ca^{2+}] = 0.01$ M; buffer $NH_3/NH_4^+$; pH = 10. Solid line: titration curve of Ca. Dotted line: titration curve of Mg. Box 1: Endpoint position without Mg-EDTA in the sample. Box 2: Endpoint position if several drops of Mg-EDTA are added.*

Many metal-ion indicators have been developed since G. Schwarzenbach and his coworkers reported that the endpoint of the EDTA titration can be marked by Murexide [10] and Eriochrome Black T [11] in the 1940s. Although the basic principle of indicating the endpoint of the EDTA titration is very similar, these dyestuffs possess different acid-base and metal complexing properties. Table 3 summarizes some common metal-ion indicators with their basic properties and applications for various EDTA titrations.

***Potentiometric Methods:*** The potentiometric method is one type of instrumental methods that is widely used in the EDTA titration. Like other instrumental methods, the potentiometric detection is superior when higher precision is required or micro-titration needs to be conducted. Potentiometric methods can be readily combined into an automated titration system, in which the endpoint can be determined by a graphical extrapolation technique that will yield better precision when the pM change around the equivalence point is not large enough for a visual method to determine.

Two types of electrodes are often used in the potentiometric detection: redox electrodes and ion-selective electrodes (ISEs). These two types of electrodes are discussed in the following.

*The Redox Electrode:* The electrical potential of a half-cell redox reaction is dependent on the concentration ratio of the reduction and oxidation states of the chemical species according to Nernst equation. At room temperature (25°C), Nernst equation is written as:

$$E = E_0 + \frac{0.0591}{z} \log \frac{[\text{Ox}]}{[\text{Red}]} \tag{30}$$

**TABLE 3 Properties and Applications of Some Common Metal-Ion Indicators**

| Indicator and Its Preparation | Chemical Name | Colors of Free Indicator Species at Different pH | Color of Metal-Indicator Complexes | Applications |
|---|---|---|---|---|
| Calmagite (0.05 g in 100 mL water. Stable for 1 year in polyethylene bottle away from sunlight) | 1-(1-Hydroxl-4-methyl-2-phenylazo)-2-naphthol-4-sulphonic acid | pH < 7, red ($H_2In^-$); | Wine red | A good substitute for Eriochrome Black T, with much better stability in aqueous solution |
| | | 8 < pH < 12, blue ($HIn^{2-}$); pH > 13, yellow orange ($In^{3-}$) | | |
| Eriochrome Black T (Solochrome Black) (0.4 g in 100 ml methanol. Stable for 1 month) | 1-(1-Hydroxy-2-naphthylazo)-6-nitro-2-naphthol-4-sulphonic acid | pH < 6, red ($H_2In^-$); | Wine red | *Direct titration* Mg, Ba, Cd, In(III), Mn, Pb, Zn and rare earths |
| | | 7 < pH < 11, blue ($HIn^{2-}$); | | *Back titration* Al, Bi(III), Ca, Co, Cr(II), Cu(II), Ni, Fe(II), Ti(IV) |
| | | pH > 12, yellow orange ($In^{3-}$) | | *Replacement titration* Au (III), Ba, Ca, Cu(II), Hg(II), Pb, Pd(II), Sr |
| Murexide | 5-[(Hexahydro-2,4,6-trioxo-5-pyrimidinyl)imino]-2,4,6 (1H,3H,5H)-pyrimidine-trione monoammonium salt | pH < 9, red-violet ($H_4In^-$); | Red with $Ca^{2+}$ | *Direct titration* Ca, Ni, Co, Cu(II) |
| | | 10 < pH < 11, violet ($H_3In^{2-}$); pH > 11, blue ($H_2In^{3-}$) | Yellow with $Co^{2+}$, $Ni^{2+}$ and $Cu^{2+}$ | *Back titration* Ca, Cr(III), Ga (III) *Replacement titration* Ag and halides |
| PAN | 1-(2-Pyridylazo)-2-naphthol | pH < 12, yellow-orange (HIn); | Red | *Direct titration* Cu(II), Zn, Cd, Sc, In(III) |

(*Continued*)

**TABLE 3** (*Continued*)

| Indicator and Its Preparation | Chemical Name | Colors of Free Indicator Species at Different pH | Color of Metal-Indicator Complexes | Applications |
|---|---|---|---|---|
| | | pH > 13, pink ($In^-$) | | *Back titration* Zn, Cd, Ni, Pb, Fe(III), Ga(III), Sc(III) *Replacement titration* Ca, Mg, Mn, Zn, Cd, Pb, In(III), Ga(III), Hg(II), V, Ni, Co |
| Pyrocatechol Violet (0.1 g in 100 mL water. Stable for many months) | 3,3′-4-trihydroxyfuchsone -2″-sulfonic acid | pH < 1.5, red ($H_4In$); 2 < pH < 6, yellow ($H_3In^-$); 7 < pH < 9, violet ($H_2In^{2-}$); pH > 10, red-purple ($HIn^{3-}$) | Blue, except red with Th (IV) | *Direct titration* Al, Bi, Ca, Cd, Co, Fe(III), In(III), Mn, Ni, Zn, Th(IV) *Back titration* Al, Bi, Ca, Cd, Co, Fe(III), In(III), Mn, Ni, Zn, Th(IV) |
| Xylenol Orange (0.5 g in 100 mL ethanol. Stable indefinitely) | 3,3′-Bis[*N*, *N*-di(carboxyl-methyl)aminomethyl]-*o*-cresolsulfonephthanlein | pH < 6.3, lemon yellow ($In^{4-}$); pH > 6.5, red/pink ($In^{4-}$) | Red/violet | *Direct titration* Bi(III), Th (IV), Sc(III), La(III), Zn, Pb, Hg(II), Ca, Co, Ta(V). *Back titration* Sn, In, Ga(III), Fe(III), Ni, Co, Cu, U(IV), V, Cr(III), Ti(IV), Zr(IV), Al, Lanthanides |

where $E_0$ is the standard potential of the redox couple. $E$ is the potential when the concentrations of the redox couple are [Ox] and [Red], respectively. $z$ refers to the number of electrons transferred in the half-cell reaction.

For metal ions such as Cu(II) and Fe(III), a reversible redox equilibrium can quickly establish between the reduced and oxidized couple of the metal (i.e., Cu(II)/Cu and Fe(III)/Fe(II)) on the surface of a chemically inert electrode (platinum or graphite). The electrode potential can be measured if it is coupled with a reference electrode (e.g., calomel electrode). The titration curve for the metal ion can be thus detected by the potential of the redox electrode. The EDTA titration of Hg(II) can be also detected by such a potentiometric method because a reversible redox equilibrium between the couple, Hg(II)/Hg, can be established on a dropping mercury electrode or an amalgamated gold electrode. Nevertheless, most of the metals do not have a reversible redox couple suitable for such a detection. The method using the redox couple of the metal to be titrated is thus limited to only a few metal ions (Cu(II), Fe (III), or Hg(II)).

However, Fe(III)/Fe(II) and Hg(II)/Hg redox couples can be used as the indicator electrode for the titration of other metal ions. This can be understood from the complexation equilibria and the Nernst equation. Take Hg(II)/Hg couple as an example, if several drops of Hg-EDTA are added in the sample for the titration of a metal, $M^{n+}$, the corresponding complexation equilbria will be:

$$K_{MY} = \frac{[MY^{n-4}]}{[M^{n+}][Y^{4-}]}, \qquad K_{HgY} = \frac{[HgY^{2-}]}{[Hg^{2+}][Y^{4-}]} \tag{31}$$

where $K_{MY}$ and $K_{HgY}$ refer to the stability constants of the EDTA complexes of $M^{n+}$ and Hg(II), respectively. Combining these equations with the Nernst equation on a dropping mercury electrode at 25°C will give

$$E_{Hg} = E^0_{Hg} + \frac{0.0591}{2}\log\left[Hg^{2+}\right] = E^0_{Hg} + \frac{0.0591}{2}\log\left(\frac{[M^{n+}]}{[MY^{n-4}]} \cdot \frac{[HgY^{2-}]K_{MY}}{K_{HgY}}\right) \tag{32}$$

If Hg-EDTA is not as stable as the EDTA complex of $M^{n+}$, Hg(II) ion will be released from its complex as soon as Hg-EDTA is added into the sample. Then, the potential of the dropping mercury electrode ($E_{Hg}$) is decided by $[Hg^{2+}]$, as shown in the first half of Eq. 32. The endpoint will occur when all of the $M^{n+}$ ion is complexed with EDTA and Hg(II) starts to combine with EDTA.

If Hg-EDTA complex is more stable than the EDTA complex of the metal ion to be titrated, the electrode potential ($E_{Hg}$) is dependent on the concentration ratio, $[M^{n+}]/[MY^{n-4}]$, as shown in the second half of Eq. 32. $[HgY^{2-}]$ is approximately constant during the titration process because only a small amount of Hg-EDTA is added. As the value of $[M^{n+}]/[MY^{n-4}]$ changes dramatically around the equivalence point, the endpoint of the titration can be easily detected by the potential change of the dropping mercury electrode.

Generally, three requirements must be met in order to use Fe(III)/Fe(II) or Hg(II)/Hg redox couple as the electrode indicator for an EDTA titration:

i. The reduction potential of the metal ion should be less than that of the redox couple. No interfering reaction occurs on the electrode. This is true to many metal ions because the reduction potentials of Fe(III)/Fe(II) (0.771 V) and Hg (II)/Hg (0.85 V) are relatively high.
ii. The medium pH should be in the range in which the complex reaction of Fe(III) or Hg(II) with EDTA is not hindered by other processes. When pH is too low (pH $< 1$ for Fe(III); pH $< 2$ for Hg(II)), the EDTA complex of these metals dissociates to such an extent that only a poorly defined titration curve can be obtained. When pH is too high (pH $> 11$), oxygen and hydroxide ions will participate into the reaction, and the titration curve is deteriorated.
iii. Interfering species such as halides, cyanides, and sulfides will form rather stable species with Hg(II) and Fe(III). The presence of these species should be avoided when the redox electrode is used for the endpoint detection.

In spite of the above limitations, the redox pairs, Fe(III)/Fe(II) and Hg(II)/Hg, have been successfully used in the EDTA titrations of many metals. Practically, a dropping mercury electrode is more useful than an Fe(III)/Fe(II) inert electrode because the latter has a problem of being easily poisoned in the titration process. The metals that are often titrated with a dropping mercury electrode include Al, Bi, Ca, Cd, Cu, Co, Pb, Zn, and Ni.

For example, a dropping mercury electrode can be used for the EDTA titration of Cd at pH 5. Before the titration, several drops of Hg-EDTA are added and an electrical cell composing of a dropping mercury electrode and a reference electrode (e.g., a calomel electrode) is inserted in the sample solution. The potential of the dropping mercury electrode ($E_{Hg}$) is recorded when standard EDTA is added in the sample under stirring. As the reduction potential of Cd(II)/Cd couple ($-0.403$ V) is much less than that of the Hg(II)/Hg couple, the potential on the dropping mercury electrode is dependent on the concentration ratio of Cd(II) and Cd-EDTA as shown in Eq. 32. When close to the equivalence point, the complexation of Cd(II) with EDTA is about to complete and the concentration of the "free" EDTA increases quickly. This causes a fast decrease in $[Cd^{2+}]$/[Cd-EDTA] ratio and a sharp decrease in the potential of the dropping mercury electrode. The endpoint can be located graphically or numerically by plotting the electrode potential ($V$) versus the percent of titration ($\phi$).

*The Ion-Selective Electrode (ISE):* In the last two decades, a great deal of efforts has been made in search of ISEs for various metal ions. This is because ISEs can be used to quickly and automatically estimate the concentration of the metal ion of interest in a solution where other metal ions and species are present. Nowadays, ISEs are available for most of the metal ions. As to common metal ions, such as Ca, Cd, Cu (II), and Pb, their ISEs are available in the market with high quality. For other metals,

including transition metals, lanthanides, and actinides, the ISEs can be readily prepared according to the procedures offered in literatures.

The key part of an ISE is the membrane that separates the sample solution from a chamber in which a reference electrode (e.g., AgCl/Ag electrode) is immersed in a solution (sometimes solid powders) of the metal ion to be detected. Although glasses or inorganic crystals are used (e.g., pH electrode), the ISE membrane is normally made of a plastic material containing a polymer (e.g., poly(vinyl chloride)), a plasticizer, an anion excluder (e.g., sodium tetraphenyl borate, NaTBP), and a complexing agent (ionophore) that has high selectivity to the metal ion to be detected. After solidified on the top of the electrode chamber, the membrane is conditioned with a solution of the metal ion to be measured. The potential of an ISE is dependent on the Gibbs energy change in the mass transfer process of the metal ion across the membrane. According to the structure and composition of the membrane, the mass transfer may have a mechanism of ion exchange, solvent extraction, etc. In a certain concentration range, the potential of an ISE is found to have a linear relationship (Nernstian response) with the logarithm of the activity of the metal ion in the sample solution. Especially, a good ISE shows high selectivity to the metal ion to be detected and much lower response to other ionic species. This is because the ionophore used in the membrane is highly selective to the target metal ion. This property makes the ISEs to be able to estimate the concentration of the target metal ion in the solution where multiple ionic species are present.

The dynamic response time of an ISE ranges from 5 to 30 s. The voltage response to the metal concentration is about 20 mV/decade. An ISE normally shows the Nernst ion response in the range from $10^{-1}$ to $10^{-6}$ M of the metal concentration. When coupled with a reference electrode, an ISE can be readily used as the indicator electrode for the EDTA titration. With the fast development of the complexing agents and ISE technology, high-quality ISEs for most metal ions have become available. Particularly, ISEs are very useful for automated titration systems, where a simple and generalized detection method is desired. Table 4 lists common ISEs with their basic properties.

Some disadvantages about the ISE technique are noticed:

i. The pH range is relatively narrow. The pH for most of the ISE membranes to work properly is between pH 3 and 10.
ii. The dynamic response time is often too long for manual titration.
iii. The ISE membranes are not durable. For many ISEs, the membrane has a life of several months. New membranes have to be made when the old ones are poisoned or physically damaged.
iv. Some ISEs are not very selective to alkali metal ions. This will cause problems because the EDTA agents are normally made of sodium or potassium dihydrogen salts of EDTA.
v. As the potential response of most of the ISEs is not lower than $10^{-6}$ M, a titration with the metal concentration less than $10^{-4}$ M may be problematic.

**TABLE 4 A List of Some Common ISEs WITH BASIC SPECIFICATIONS**

| ISE | Membrane/ Ionophore– | Conc. Range (M) | pH Range | Slope (mV/decade) | Resp. Time (s) | Interference |
|---|---|---|---|---|---|---|
| Ca-ISE [12] | Polymer | $1–5 \times 10^{-6}$ | 3–10 | $27 \pm 2$ | 30 | Pb(II), Hg(II), Cu(II), and Ni. |
| Cd-ISE [12] | Solid state | $0.1–5 \times 10^{-7}$ | 2–12 | $57 \pm 2$ | 20 | Ag, Hg(II), Cu(II). High conc. of Pb(II) and Fe(II). |
| Cu-ISE [12] | Solid state | $0.1–5 \times 10^{-8}$ | 2–12 | $27 \pm 2$ | 20 | Ag, Hg(II), high conc. of $Cl^-$, $Br^-$, Cd(II) and Fe(II). |
| Pb-ISE [12] | Solid state | $0.1–5 \times 10^{-6}$ | 3–8 | $25 \pm 2$ | 20 | Ag, Hg(II), Cu(II). High conc. of Pb(II) and Fe(II) |
| Al-ISE [13] | PVC/Morin | $0.1–5 \times 10^{-7}$ | 3.5–5 | $19.7 \pm 0.1$ | 5 | High conc. of Fe(III), Cr(III), K, Na. |
| Co-ISE [14] | PVC/calixarene | $0.1–5.3 \times 10^{-6}$ | 2.5–6.0 | $30 \pm 0.1$ | 10 | High conc. of Zn, Hg(II), Pb(II), Ag, Ni, Cr(III). |
| Cr-ISE [15] | PVC/AHMTO | $0.1–1.0 \times 10^{-6}$ | 2.7–6.6 | $19.7 \pm 0.3$ | $<10$ | High conc. of Al, La, VO(II), Cu(II), Ce(III). |
| Cu-ISE [16] | PVC/Porphyrin | $0.1–4.4 \times 10^{-6}$ | 2.8–7.9 | $29.3 \pm 0.2$ | 8 | Ni, High conc. of Cd, Sr, K. |
| Dy-ISE [17] | PVC/BBH | $0.01–1.0 \times 10^{-6}$ | 3.0–8.0 | $20.1 \pm 0.8$ | $<20$ | Na, Yb(III), Tm, Ho. |
| Gd-ISE [18] | PVC/PyTu4NO2 | $0.1–1.0 \times 10^{-7}$ | 4.0–9.0 | $20.0 \pm 0.3$ | 10 | High conc. of Sm, Eu, Yb. |
| La-ISE [19] | PVC/NPYFH | $0.1–1 \times 10^{-6}$ | 3.5–10 | $19.2 \pm 0.6$ | 10 | High conc. of Sm, Nd, Eu, Yb(III). |
| Lu-ISE [20] | PVC/TPD | $0.01–1 \times 10^{-6}$ | 4.5–8 | $20.5 \pm 0.4$ | $<10$ | Nd, high conc. of Dy, Cu(II), Ho. |
| Ni-ISE [21] | PVC/NED | $0.1–5 \times 10^{-6}$ | 3.6–7.4 | $29.9 \pm 1$ | 20 | Na, K, Ba, Zn, Ag, Hg(II), Pb(II). |
| Pr-ISE [22] | PVC/PBH | $10^{-3}–10^{-8}$ | 3.0–8.5 | 21.1 | 10 | No interference. |
| Sm-ISE [23] | PVC/SnBP | $0.1–1 \times 10^{-5}$ | 4.0–10 | $40 \pm 0.9$ | $<10$ | No interference. |
| Sr-ISE [24] | PVC/Calixarenes | $0.1–3.2 \times 10^{-5}$ | 3–10 | 30 | 10 | Pb(II), Cd(II), Zn, Cs, high conc. of other metal ions. |
| Tb-ISE [25] | PVC/ATO | $0.1–1 \times 10^{-6}$ | 3.8–8.2 | $19.4 \pm 0.5$ | 15 | High conc. of Ga(III), Ni, Na. |
| Th-ISE [26] | PVC/DPTD | $0.01–1 \times 10^{-6}$ | 3.0–9.0 | $15.2 \pm 0.5$ | 30 | No interference. |
| Tm-ISE [27] | PVC/DADS | $0.01–1 \times 10^{-6}$ | 4.8–8.5 | $19.5 \pm 0.3$ | $<15$ | Er, Lu, Pb(II), Yb(III), Pr |
| V-ISE [28] | Graphite/NTHA | $2 \times 10^{-3}–1 \times 10^{-6}$ | 6 | – | – | Cr(III), Mo(III), Co(II). |
| Yb-ISE [29] | PVC/PMTO | $0.1–1 \times 10^{-6}$ | 3.3–8.0 | $19.5 \pm 0.3$ | 10 | High conc. of Sm, La, Cd, Na |

## 8 TYPES OF EDTA TITRATIONS

As discussed in previous sections, all EDTA titrations are based on the same principle – formation of stable 1:1metal-EDTA complexes and detection of the equivalence point at which an equal amount of the metal and EDTA are combined. However, such an ideal procedure is often complicated under practical circumstances by the factors including slow kinetics of metal-EDTA complexation, "blocking" effect of trace metals on the endpoint detection, hydrolysis of the metal ion, and existence of multiple metal ions and other chemical species. Accordingly, various procedures have been developed to deal with the analytical tasks in the real world. These procedures include direct titration, back titration, replacement titration, selective titration, and indirect titration. The selective titration can be further divided into pH-adjustment, masking with agent, and kinetic masking. All these approaches will be discussed in the following.

***Direct Titration:*** The simplest procedure is to directly titrate the sample with standardized EDTA. Except at very low or very high pH (pH $< 2$ or pH $> 12$), the addition of a pH buffer ($HAc/Ac^-$ for ~pH 5, Hexamine for ~pH 6, $NH_3/NH_4NO_3$ for ~pH 10) is generally necessary to control the pH in a narrow range. If the titration needs to be conducted at a pH where the hydrolysis of metal ion is significant, an auxiliary complexing agent (e.g., ammonia water, citrate, tartrate, and triethanolamine) is added to prevent the hydrolysis. It is noted that when the titration is needed to be conducted in the pH range between 9 and 10, concentrated ammoniacal solution is often used as the pH buffer as well as the auxiliary complexing agent. For example, Zn, Cd, Ni, and Cu(II) ions can form soluble ammine complexes at pH 10 and be successfully titrated with EDTA.

It is not always straightforward to find a suitable endpoint detection method for a direct titration. For some metals, one may run into a problem that the metal-ion indicator does not produce a sharp color change at the endpoint. A valuable way to deal with this problem is to add several drops of the EDTA complex of another metal that can give a sharp color change at the endpoint. Similarly, if the metal to be titrated does not have a reversible redox couple for the potentiometric detection, Fe(III)/Fe(II) or Hg(II)/Hg reversible redox couple may be used to potentiometrically detect the endpoint. It is noted that the metal added for the endpoint detection is normally in its EDTA complex form, which makes it unnecessary to correct the titration result because the second metal added for the endpoint detection will not consume any EDTA in the titration. Such method is called "partial replacement titration," and will be discussed in detail in the following section.

Some trace metals contained in a sample can "block" certain metal-ion indicators. For example, trace amount of copper combines irreversibly with Eriochrome Black T and hinders the use of this indicator in the direct titration of Ca, Mg, Ba, and Sr. Under such situations, an agent complexing more strongly with the trace metal is often added to prevent the trace metals from interfering with the indicator. Such a complexing agent is called "masking agent." For example, trace metals such as Ag, Cd, Co, Cu(II), Hg(II), Ni, Pd(II), Pt, and Zn can be masked by potassium cyanide. A reducing agent such as ascorbic acid or hydroxylamine can change the oxidation states of some

oxidative metal ions (Cr(III), Fe(III), Cu(II), etc.) and protect the indicators from being "blocked" by these metal ions. When a masking agent is used, enough time should be permitted for the masking reactions to occur. After that, the indicator can be added for the direct titration.

Slow kinetics often occur to the reactions between the metal ion and EDTA or between the metal ion and the metal-ion indicator. A direct titration may be influenced by such slow kinetic processes. An easy solution to this problem is to heat the sample solution and keep it at an elevated temperature during the titration. For example, in the direct titration of Mg, a sharp color change will appear at the endpoint only when the titration is conducted at an elevated temperature (>50°C). This is because the Mg-EDTA complex forms at a slow rate and causes the titration sluggish at room temperature.

Table 5 lists typical direct EDTA titrations for some metal ions. The titration procedures in Table 5 are arranged in the ascending order of the medium pH at which the titration is conducted. Common masking agents used to remove the interference under various situations are also listed in the table. Further discussion on utilizing masking agents is included in the section "Use of Masking Agents." In Table 5, only metal-ion indicators are listed as the endpoint detection method. However, other methods such as the potentiometric methods with redox electrodes or ISE electrodes can also be used in many titrations listed in the table. The basic properties of common ISEs can be found in Table 4.

***Back Titration:*** Back titration is a procedure designed to overcome most of the difficulties encountered in direct titration. A back titration is composed of two basic steps: i) add an excess amount of EDTA to the sample and ii) "back-titrate" unreacted EDTA with a standard metal solution under a suitable condition. Both of the EDTA agent and the back-titration metal solution employed in the back titration should be standardized. It is worthwhile to note that the EDTA complex of the metal ion used to back-titrate the excess EDTA should be less stable than that of the metal to be determined. Otherwise, the latter may be replaced from its EDTA complex in the process of titration.

As the metal to be determined is complexed with EDTA before the titration, problems such as the formation of insoluble hydroxides, the existence of trace metals that block the endpoint indicator, and the slow kinetic processes of complexing reactions no longer affect the titration. This is the reason why the back titration can overcome most of the difficulties encountered in the direct titration.

For example, Al and Zr(IV) are readily hydrolyzed in pH 9–10, which is the proper range for a direct titration with Eriochrome Black T. The metal hydrolysis leads to a sluggish endpoint color transition and large analytical error. If a back titration is employed, excess amount of EDTA is added in the sample at lower pH to ensure a complete complexation (with boiling); then the unreacted EDTA is titrated with a standard Mg solution at pH 10. For example, metal ions, including Cu(II), Ni, and Co, form complexes with Eriochrome Black T that are more stable than the complexes with EDTA. This makes the indicator unsuitable for the direct titration of the above metal ions. With a back titration, excess amount of EDTA is added before the addition of the indicator. Then, the unreacted EDTA can be titrated by Pb, Zn, or Mg standard solution, using Eriochrome Black T as the indicator.

**TABLE 5 Typical Direct Titrations for Some Metal Ions**

| Metal Ion | pH | Buffer | Endpoint Detection Method | Remarks |
|---|---|---|---|---|
| Zr(IV) | <1 | HCl | Eriochrome Black T (b/r) [30] | Boil the acidic solution before titration. Ascorbic acid reduces Hg(II) and Fe(III). Sulfate masks Th and Ti(IV). |
| | | $HNO_3$<br>$H_2SO_4$ | Xylenol Orange (r/y) [30] | |
| Bi(III) | 1–3 | $HNO_3/NO^-_3$ | Xylenol Orange (r/y) [31] | Ascorbic acid reduces Hg(II) and Fe(III). Sulfate masks Th (IV) and Ti(IV). Fluoride masks Al, Ba, Be, Fe(III) (in small amount), Mg, Nb, rare earths, Sr, Ta(V), Ti(IV), and Zr(IV). |
| | | | Pyrocatechol Violet (b/y) [32]<br>PAN (r/y) | |
| VO(II) | 2 | $HClO_4/ClO_4^-$ | Xylenol Orange (r/y) [30] | Phosphate masks W(IV). |
| Sc(III) | 2–3 | $HAc/Ac^-$ | Cu-PAN (r/y) [30]<br>Murexide (y/v) [30] | |
| Th(IV) | 2–3 | $HAc/Ac^-$ | Xylenol Orange (r/y) [31] | Ascorbic acid reduces Hg(II) and Fe(III). $H_2O_2$ masks W(IV). 2,3-Mercaptopropanol-1 masks Bi and Pb at pH 3. |
| | | | Methylthymol blue (b/y) [31]<br>Pyrocatechol Violet (r/y) [30] | |
| Tl(III) | 2–5 | $HAc/Ac^-$ | PAN (R/Y) [30]<br>Xylenol Orange (r/y) [30, 31] | Heat the solution to 80°C. |
| Fe(III) | 2–5 | $HAc/Ac^-$ | Xylenol Orange (r/y) [32]<br>Pyrocatechol Violet (r/b) [32]<br>Sulphosalicylic acid (v/c) [33]<br>Cu-PAN (r/y) [32] | $H_2O_2$ masks W(IV). Thiourea masks Cu(II). |
| In(III) | 2–4 | $HAc/Ac^-$ | Cu-PAN (r/y) [34, 35] | Ascorbic acid reducees Hg(II) and Fe(II). Cyanide masks Ag, Cd, Co, Cu(II), Hg(II), Ni, Pd(II), Pt, and Zn. Fluoride masks Al, Ba, Be, Ca, Fe(III) (in small amount), Mg, Nb, rare earths, Sr, Ta, Ti(IV), and Zr(IV). Formic acid or formaldehyde reduces Tl(III). |

| Zn | 6 | Hexamine | Xylenol Orange (r/y) [30, 31] | Fluoride masks Al, Ba, Be, Ca, Fe(III) (in small amount), Mg, Nb, rare earths, Sr, Ta, Ti(IV), and Zr. Ascorbic acid reduces Cu(II). Citrate masks Al, Sn(II), Th, and Zr. |
| | | | Cu-PAN (r/y) [30, 35] | |

| | | | | |
|---|---|---|---|---|
| Sn(II) | 6 | Hexamine | Xylenol Orange (r/y) [31] | |
| Ni | 7–10 | $NH_3/NH_4^+$ | Murexide (y/v) [30, 31, 38], Bromophyrogallol red (b/r) [31]. | Triethanolamine masks Al, Fe(III), Sn(IV), and Ti(IV), and small amount of Mn. $H_2O_2$ masks W(IV). Citrate masks Al, Sn(II), Th, and Zr. Tartrate masks Sb(III), Sn(IV), and Zr(IV). |
| Zn | 8-9 | $NH_3/NH_4^+$ | Murexide (y/v). | Fluoride masks Al, Ba, Be, Ca, Fe(III) (in small amount), Mg, Nb, rare earths, Sr, Ta, Ti(IV), and Zr(IV). Ascorbic acid reduces Cu(IV). Citrate masks Al, Sn(IV), Th(IV), and Zr (IV). Carbonate masks U(IV). |
| Ga(III) | 9 | $NH_3/NH_4^+$ | Eriochrome Black T (r/b) [30]. | Fluoride masks Al, Ba, Be, Fe(III) (in small amount), Mg, Nb, rare earths, Sr, Ta, Ti(IV), and Zr(IV). |
| Mn(II) | 10 | $NH_3/NH_4^+$ | Eriochrome Black T (r/b) [31, 39] | Add some ascorbic acid or hydroxylamine to prevent oxidation and precipitation. |
| In(III) | 8–10 | $NH_3/NH_4^+$ | Eriochrome Black T (r/b) [30, 40] Pyrocatechol Violet (b/y) [30] | Add tartrate to prevent precipitation. Boil the solution before titration. Ascorbic acid reduces Hg(II) at pH 2. Cyanide masks Cd, Co, Cu(II), Hg(II), Ni, Pd(II), Pt, and Zn. Fluoride masks Al, Ba, Be, Ca, Fe(III) (in small amount), Mg, Nb, rare earths, Sr, Ta, Ti(IV), and Zr(IV). |
| Zn | 10 | $NH_3/NH_4^+$ | Eriochrome Black T (r/b) [30, 31] | Fluoride masks Al, Ba, Be, Ca, Fe(III) (in small amount), Mg, Nb, rare earths, Sr, Ta, Ti(IV), and Zr(IV). Ascorbic acid reduces Cu(II). Citrate masks Al. Carbonate masks U(IV). |
| Mg | 10 | $NH_3/NH_4^+$ | Eriochrome Black T (r/b) | |
| Ba | 12 | $NH_3/NH_4^+$ | Methylthymol blue (r/gr) [31] | Cyanide masks Cd, Co, Cu(II), Hg(II), Ni, Pd(II), Pt, and Zn. Citrate masks Al, Sn(II), Th(IV), and Zr(IV). Carbonate masks U(IV). Tartrate masks Sb(III), Sn(IV), and Zr(IV). |
| Ca | $>12$ | NaOH | Murexide (r/v) [30,38] Methylthymol blue (r/gr) [31] | Cyanide masks Cd, Co, Cu, Hg, Ni, Pd(II), Pt, and Zn. Citrate masks Al, Sn(II), Th(IV), and Zr(IV). Carbonate masks U(IV). Tartrate masks Sb(III), Sn(IV), and Zr(IV). |

Note: The color change of each metal-ion indicator is shown by the characters with the meanings: r = red; b = blue; y = yellow; gr = gray; v = violet.

Furthermore, many metal ions such as Cr(III), Ti(IV), and U(IV) complex with EDTA at slow rates, making the direct titration of these metal ions very difficult to conduct. If excess amount of EDTA is added and the sample solution is boiled for enough time, the metal to be titrated will be completely complexed with EDTA. Then, the unreacted EDTA can be readily titrated with a standard metal solution under a suitable condition.

In a back titration, the procedure to titrate the excess EDTA should be easy to operate and produce a sharp signal for the endpoint. The titration procedures frequently used at different pH are listed in the following:

Proc. (i): Back titration at pH 2–3 with Xylenol Orange. Adjust to pH 2–3 with a strong acid. Titrate the excess EDTA with a standard Th(IV) solution using Xylenol Orange. The color changes from yellow to red at the endpoint.

Proc. (ii): Back titration at pH 4–6 with PAN or Xylenol Orange. Adjust to pH 4–6 with $HAc/Ac^-$ buffer or hexamine powders. Titrate the excess EDTA with a standard Cu(II) or Zn solution using PAN or Xylenol Orange. The color changes from yellow to red at the endpoint.

Proc. (iii): Back titration at pH 5–7 with Pyrocatechol Violet. Adjust to pH 5–7 with $HAc/Ac^-$ buffer. Titrate the excess EDTA with a standard Zn, Cu(II), or Pb solution using Pyrocatechol Violet. The color changes from yellow to blue at the endpoint.

Proc. (iv): Back titration at pH 7–9 with Murexide. Adjust the solution to pH 7–9 with hexamine or buffer. Titrate the excess EDTA with a standard Ni, Co, Zn, or Cu(II) solution using Murexide. The solution changes from red to yellow.

Proc. (v): Back titration at pH 9–10 with Eriochrome Black T. Adjust the solution to pH 9–10 with buffer. Boil the solution and titrate the excess EDTA with a standard Mg, Zn, or Pb solution using Eriochrome Black T. The solution changes from blue to red.

Table 6 lists the back titrations for some metal ions. In the table, the titration procedures used to determine the unreacted EDTA are listed as Proc. (i), Proc. (ii), etc., corresponding to the procedures summarized above. More examples of back titrations can be found in literatures [30, 31].

***Replacement Titration:*** This procedure is also called substitution titration or displacement titration. In a replacement titration, an excess amount of the EDTA complex of the replacement metal is added to the sample. Equivalent amount of the replacement metal will be liberated from its EDTA complex by the metal ion to be determined, and the metal liberated is titrated with EDTA under a proper condition. The replacement metal should meet the following conditions: (*i*) its EDTA complex is less stable than that of the metal to be determined and (*ii*) a good endpoint detection method is available for the direct titration of the replacement metal.

The replacement titration is similar as the back titration in that both procedures employ the complexation between EDTA and a second metal as the titration reaction, and both procedures can overcome the problems in the direct titration. However, in a

Formic acid or formaldehyde reduces Tl(III). |
| Co | Add excess EDTA and adjust to pH 9–10. | Proc. (v) | Citrate masks Sn(II), Th(IV), and Zr(IV). Pyrophosphate masks Cr(III) and Fe(III). Tartrate masks Sb(III), Sn(IV), and Zr(IV). Thosulfate masks Cu(II). Triethanolamine masks Al, Fe(III), Sn(IV), and Ti(IV). |
| Ni | Add excess EDTA. | Proc. (v) | Triethanolamine masks Al, Fe(III), Sn(IV) and Ti(IV), and small amount of Mn. $H_2O_2$ masks W(IV). Citrate masks Al, Sn(II), Th(IV), and Zr(IV). Tartrate masks Sb(III), Sn (IV), and Zr(IV). |
| Ca | Adjust to pH 10 and add excess EDTA. | Proc. (v) | Cyanide masks Cd, Co, Cu, Hg(II), Ni, Pd(II), Pt, and Zn. |

replacement titration, there is no need to accurately quantify the amount of the metal-EDTA agent added in the sample. This simplifies the procedure. Compared with the back titration, replacement titration may yield smaller analytical error because only the EDTA agent for the titration needs to be accurately quantified.

Mg-EDTA solution is the most common replacement agent because Mg-EDTA complex is less stable than the EDTA complexes of most metal ions. Mg is readily titrated at pH 10 at an elevated temperature (>50°C), using Eriochrome Black T as the metal-ion indicator. Mn-EDTA and Zn-EDTA solutions are also useful for the replacement titration of the metals that form more stable EDTA complexes.

Sometimes a complex other than metal-EDTA is used in the replacement titration. Such an arrangement can be used to titrate the species that does not form stable complexes with EDTA. For example, a nickel complex, $Ni(CN)_4^{2-}$, is used as the metal complex in the replacement titration of silver ion. As $Ag(CN)_2^-$ is much more stable than $Ni(CN)_4^{2-}$ (at 25°C, $K(Ag(CN)_2^-) = 10^{20.4}$, $K(Ni(CN)_4^{2-}) = 10^{31.3}$), the following replacement reaction will occur quantitatively:

$$Ni(CN)_4^{2-} + 2Ag^+ \rightleftharpoons 2Ag(CN)_2^- + Ni^{2+} \tag{33}$$

The nickel liberated from its cyanide complex can be directly titrated with EDTA, and the silver can be determined from the stoichiometry of the above reaction. Since the cyanide complexes of both Ni and Ag are much more stable than their EDTA complexes, the cyanide complexes will not interfere with the titration. Therefore, the requirements for the second complexing agent used in the replacement titration can be summarized as follows: (*i*) its complexes with both of the metal ions are more stable than the corresponding metal-EDTA complexes and (*ii*) its complex with the metal ion to be determined is more stable than that with the replacement metal ion.

If poor endpoint detection is the only reason for using the replacement titration, a complete replacement is not necessary. A partial replacement titration that uses a small amount of the EDTA complex of the displacement metal is quite enough to give a sharp endpoint signal. For example, Cu-PAN, a widely used metal-ion indicator, is actually an agent using the principle of partial replacement titration. Cu-PAN is a solution containing Cu-EDTA complex and PAN indicator. As Cu-PAN complex is rather stable, many metal ions can replace Cu from its EDTA complex to lead to the formation of Cu-PAN complex, which has a bright-red color. At the equivalence point, when the first drop of excess EDTA is added, EDTA will replace PAN from Cu-PAN complex. The solution color is turned from red into yellow, which is the color of PAN indicator itself.

***Selective Titration:*** The EDTA titrations of a single metal ion are relatively simple and easy to operate. Difficulties may be encountered if the sample contains multiple metal ions and if multiple metal ions existing in one sample are to be titrated. Theoretically, a metal ($M_I$) can be selectively titrated in the presence of the second metal ($M_{II}$) only when

$$\frac{K'_{M_I Y}}{K'_{M_{II} Y}} > 10^8 [M_{II}] \tag{34}$$

where $K'_{M_IY}$ and $K'_{M_{II}Y}$ are the conditional stability constants for $M_I$ and $M_{II}$, respectively. $[M_{II}]$ is the molarity of the second metal ion. Such a condition is often unsatisfied as to the samples in real world. Extra measures have to be taken to selectively titrate the metal ion coexisting with other metal ions.

Most of the selective titration procedures are based on the addition of a chemical agent to alter the selectivity of EDTA over the metals in question. These procedures, including pH-adjustment, masking with agent, and kinetic masking, will be discussed in the following. Other procedures, mainly based on the separation of metals into different phases before titration, are principally not selective titrations and will not be discussed in this section.

*pH-Adjustment:* It can be seen from Table 1 the stability constants of EDTA complexes of the metal ions can be roughly divided into three groups:

| | |
|---|---|
| Tri- and tetravalent metal ions, including Co(III), V(III), In(III), Th(IV), Fe(III), Sc, Hg(II), Ga, Zr(IV), etc. | Log $K > 20$ |
| Divalent transition metals, rare earths, Pb, Al, U(IV), Ti(IV), etc. | $19 > \log K > 12$ |
| Alkaline earths | $11 > \log K$ |

From Fig. 4, one can see that the metals in the first group can be titrated at pH as low as pH 1–3. The second group can be titrated at pH as low as pH 4–6, and the third group can be titrated only in the range of pH 8–11. This suggests that a sample containing metals from different groups may be successively titrated by controlling the medium pH. However, it is noticed that difficulties may occur discerning several endpoints when more than one metal-ion indicators are used. The colors of multiple indicators often interfere with each other to make the visual detection impossible. Under such circumstances, detection methods such as potentiometric methods become important complementary methods for a sequential titration of multiple metal ions.

For example, a mixture of Bi(III), Pb, and Mg can be sequentially titrated by controlling the pH. At acidic medium (pH 1–2), Bi(III) can be directly titrated with a Fe (III)/Fe electrode and several drops of Fe-EDTA complex for the detection of the endpoint. Then, the solution is adjusted to pH 5 with $HAc/Ac^-$ buffer and Pb can be directly titrated with the Fe(III)/Fe electrode or a Pb-ISE. Finally, the solution is brought up to pH 10 with ammoniacal buffer and heated to $>50°C$. The Mg is directly titrated with Eriochrome Black T, which changes color from red to blue at the endpoint.

In a few cases, one metal-ion indicator is effective in a wide pH range and can be used to detect several endpoints. This makes it possible to conduct some sequential EDTA titrations with a single metal-ion indicator, without running into the trouble of color interference due to multiple metal-ion indicators. For example, a sample composed of a trivalent/tetravalent metal ion (Th(IV), Fe(III), or Bi(III)) and a bivalent metal ion (Zn, Pb, Cd, or Co) can be successively titrated using Xylenol Orange as indicator. As to such a sample, the solution is first adjusted to pH 1–3 and the trivalent/tetravalent metal ion is titrated. At the endpoint, Xylenol Orange is replaced by EDTA from the metal complex and it changes from red to yellow. Then,

the solution is neutralized, and hexamine powders are added to control the solution at pH 6. The solution turns into red again as Xylenol Orange complexes with the divalent metal ion. The divalent metal ion can be directly titrated, and the color changes to yellow at the endpoint.

*Masking with Agent:* A masking agent is a substance that can selectively "mask" certain metals from complexing with EDTA and make it possible for the titration of some other metals. According to the mechanism of the process, the masking processes can be sorted as complexation masking, redox masking, and precipitation masking. Since the pH-adjustment is an approach to alter the EDTA selectivity over metals by changing the proton concentration, it can be considered as one of the masking processes as well.

The agents used for complexation masking are fluoride, cyanide, citrate, tartrate, 2-mercaptoethanol, triethanolamine, etc. For example, tartrate can mask Al, Fe(III), Nb (V), Ta(V), Ti(IV), W(VI), Sb(III), and Sn(IV), enabling the titration of Zn, Bi, Cd, Co (III), Cu(II), Ni, rare earths, and alkaline earths. Ammonium fluoride can mask Al, Ca, and Mg to enable the determination of Bi(III), Cd, Cu(II), Ga(III), In(III), Mn, Ni, Pb, and Zn.

Cyanide ion is one of the effective complexation masking agents. At $pH > 8$, cyanide ion forms stable complexes with the metal ions such as Cd, Zn, Hg(II), Cu(II), Co, Fe(II), Fe(III), Ni, Hg(II), Ag, Pd(II), Tl(III), and Pt(II), but do not interact with alkaline earths, Mn(II), and Pb. Therefore, the metal ions in the latter group can be selectively titrated at alkaline medium where the metals in the former group are masked by cyanide.

Moreover, Cd and Zn can be de-masked from their cyanide complexes by the addition of formaldehyde at room temperature. Formaldehyde liberates Cd and Zn from their cyanide complexes by forming glycolonitril, $HOCH_2CN$, with cyanide ion. Other metals will not be affected unless large excess amount of formaldehyde is added. This property can be used to determine Cd or Zn in the sample in which cyanide has to be added as masking agent.

Two points should be noticed when cyanide is used as masking agent: First, cyanide can only be used in alkaline medium because of its formation of deadly gas HCN in acidic medium. Before the addition of the cyanide agent, the sample solution should be brought to alkaline pH. This may lead to the formation of the metal hydroxides that are difficult to decompose. To avoid such a problem, tartaric acid or other complexing agent is added before raising the medium pH. Then, cyanide is added to combine with the metal ions to form stable cyanide complexes. Second, Fe-cyanide complex can oxidize some metal-ion indicators including Eriochrome Black T. If Fe(III) exists, the alkaline solution is usually boiled with ascorbic acid to reduce Fe(III)-cyanide complex to Fe(II)-cyanide complex before titration.

The agents used for redox masking include ascorbic acid, hydrazine, formaldehyde, hydrogen peroxide, etc. For example, ascorbic acid can reduce Fe(III) to Fe(II) and Tl(III) to Tl(I), masking these metals from interfering with the titration of In(III), Bi(III), Th(IV), or Zr(IV). Cu(II) may be reduced in acidic solution using hydrazine so that Ni or Co can be titrated without interference from the Cu(II).

A typical example of precipitation masking is to titrate Ca at high pH while Mg precipitates as $Mg(OH)_2$. Masking by precipitation is only used in a few of favorable

cases. This is because analytical error is likely to be introduced by co-precipitation, post-precipitation, and other processes related with precipitates. The precipitation can also obscure the color change at the endpoint. In many titrations involving precipitation, separation of the precipitates from the solution before the titration is proven to be valuable. As chemical separation is not considered as selective titration, such techniques are not discussed in this section.

Table 7 lists common masking agents and their applications. More detailed discussions can be found in literatures [30, 31].

*Kinetic Masking:* Sometimes, a selective titration can be devised by taking the advantage of the difference in the kinetic rates of the complexation reactions. For example, Cr(III), in spite of its high stability constant with EDTA, has a very slow rate reacting with EDTA at room temperature. One has to boil the solution with excess EDTA for >15 minutes to transfer Cr(III) completely into Cr-EDTA complex. This property allows Fe(III) or Bi(III) to be titrated in the presence of Cr(III) at pH 1–3 and room temperature. Cr(III) can be determined by a back titration after the sample is boiled with excess EDTA at pH 4 [41].

The slow rate of replacement of Ni from its EDTA complex can be used in kinetic masking as well. In ice-cold solution, Co, Zn, Cd, and Pb can be rapidly replaced from their EDTA complexes by Bi(III). But Ni is only replaced at a very slow rate. This property permits the determination of Ni in the presence of other metal ions [42].

***Indirect Titration:*** The EDTA titration can be used not only to measure the metal ions that form stable 1:1 metal-EDTA complexes but also to measure many other species, including anions, alkali metals, and organic molecules. Theoretically, any species can be determined by an EDTA titration if this species can quantitatively form a compound with a metal ion that can be determined by an EDTA titration and if this compound can be quantitatively separated from the sample. By titrating the metal containing in the compound or the excess metal after the formation of the compound, the species of interest can be determined. For quantitative analysis, the compound containing the metal and the species is often a solid and is separated from the solution before the EDTA titration.

For example, sulfate ion can be determined by first precipitating with a known amount of barium and then titrating the excess Ba with EDTA in the supernatant after the precipitates are separated. Halides or thiocyanate anions can be determined using such an approach: the species is first precipitated with silver ion. Then, the precipitates are isolated and dissolved in a $K_2Ni(CN)_4$ solution at pH 10. Each Ni(II) ion will be liberated by two silver ions in the precipitates. Nickel is titrated with EDTA using Murexide as indicator. The amount of the species can be determined by the stoichiometric relationship between Ni and the species. As to phosphate ion, it can form crystalline precipitates ($MgNH_4PO_4 \cdot 6H_2O$) with Mg and $NH_3$ in a hot solution. After being separated from the sample solution and washed with $NH_3$ water, the precipitates can be dissolved in hydrochloric acid. The Mg from the precipitates can be titrated by direct titration in a warm solution (>50°C) at pH 10 with Eriochrome Black T as indicator. Detailed discussions on the indirect titrations of many other chemical species can be found in literatures (30, 31).

**TABLE 7 Common Masking Agents and Their Behaviors in EDTA Titrations**

| Masking Agent (Type of Masking) | Metal Ions That Can Be Masked | Metal Ions That Can Be Titrated with the Masking Agent |
|---|---|---|
| Ascorbic acid (redox masking) | Cr(III) (in boiling acidic solution), Tl(III), Ti (IV), Cu(II) → Cu(I) (in alkaline medium), Fe(III) → Fe(II) (at pH 2), Hg(II) → Hg (at pH 2) | Ca, Mg, Mn, Ni, Zn, Co, Pb, Al, V(IV), Bi (III), Th(IV), $UO_2$(II), Zr(IV), Ga(III), In(III), and Pd(II) |
| Citrate (complexation masking) | Al (in small amount), Fe(III), Mo(VI), Sn (II), Th(IV), and Zr(IV) at pH 8.5 ~ 9.5 | Zn, Cd, Cu(II), Pb, Co, and Ni |
| Cyanide (complexation masking) | Cu(II), Ag, Cd, Co, Fe(III), Fe(II), Hg(II), Ni, Pd(II), Pt(II), and Zn in alkaline solution. To prevent the precipitation of the metal ions, add tartaric acid before increasing the pH. Cd and Zn can be demasked by adding formaldehyde at room temperature. Ferricyanide ion needs to be reduced with ascorbic acid because the former can oxidize many azo dye indicators. | Al, Ca, Mg, Mn(II), Pb(II), Sr, In(III), and Zn. |
| Fluoride (complexation masking) | Al, alkaline earths, rare earths, Nb, Ta, Ti (IV), Au(III), Sn(IV), and Zr in neutral and alkaline media | Zn, Ga, In, Bi(III), Cd(II), Cu(II), Mn(II), Ni (II), and Pb(II). Add tartrate to prevent these metal ions from forming insoluble hydroxides at higher pH. |
| Hydrazine (redox masking) | Fe(III) → Fe(II), Cu(II) → Cu(I), Mo(VI) → Mo(V) in acidic and neutral media | Bi(III), Ni(II), Th(IV), Mo(V) |
| Hydrogen peroxide (redox masking) | Hg(II) when pH > 2 | Cu(II), Zn |
| Iodide (complexation masking) | | |

## 9 SOME PRACTICAL CONSIDERATIONS

Although EDTA titration procedures are generally easy to carry out, some operational mistakes frequently happen and produce unpredictable errors in the analytical results. It is worthwhile to pay attention to the following points in the practical operation of EDTA titrations:

i. Many metal-ion indicators are very sensitive to even trace amount of heavy metals. De-ionized water should be always used in the preparation of all solutions for the titration.
ii. The medium pH is critical for the EDTA titration. Many titrations are required to be operated in a narrow pH range. It is suggested to use a calibrated pH meter for the pH adjustment. If a titration is carried out in a strong acidic or strong basic medium where no pH buffer is used, the pH should be monitored as the titration is close to the endpoint. When adjusting pH from acidic to alkaline, a good approach is to carefully bring the pH to neutrality with NaOH or KOH before adding the pH buffer. By doing this, the pH buffer can effectively control the solution within the correct pH range.
iii. The concentration of the metal ion to be titrated is generally controlled between 0.01 and 0.001 M. If the sample concentration is too high, the titration is often deteriorated by complicated chemical processes and blunt endpoint. On the other hand, the metal ion at very low concentration could be titrated if the stability constant of the metal-EDTA complex is sufficiently large and proper endpoint detection methods are available. The concentration effect on the titration curve is discussed in the section "Concentration Effect."
iv. The amount of metal-ion indicator to be added should be the least amount that gives discernable color changes for the titration operator. Generally, this amount is about 2–4 drops of a liquid indicator, or 20–50 mg of a solid indicator. It is noted that too much indicator gives a sharper color change at the endpoint but introduces larger analytical error due to the consumption of the metal ion by the indicator itself.
v. The standard agents, metal-EDTA solutions, and pH buffers for the EDTA titration should have the exact concentration and composition as they are meant to. Good preparation procedures should be followed to make these solutions so that unnecessary errors will not be introduced. Table 8 lists the standard procedures of preparing some agents for the EDTA titration.

## 10 SOME EXAMPLES OF EDTA TITRATIONS

### 10.1 Determination of Bi(III): DIRECT TITRATION AT pH 1-3

*Procedure:* Dilute the sample into a 250-mL volumetric flask. Pipette a 25.00-mL aliquot into a 250-mL conical flask. Monitor pH with a pH meter. If necessary adjust to

**TABLE 8 Preparation Procedures of Some Agents for the EDTA Titration**

| Agent | Preparation |
|---|---|
| 0.01 M EDTA disodium solution | Dissolve and dilute 3.722 g of sodium dihydrogen ethylenediaminetetraacetate dehydrate into a 1000-mL volumetric flask with de-ionized water. Transfer the solution to a polyethylene bottle for storage. |
| Standard EDTA disodium solution | An EDTA solution can be standardized by titrating with a standard Zn, Cu, or Pb solution. For example, when a standard Zn solution is used for standardization, 25.00 mL Zn solution is neutralized with NaOH and mixed with 5 mL of pH 10 ammoniacal buffer solution. Add 2 drops of Eriochrome Black T solution and titrate with the EDTA solution. |
| 0.0100 M standard $ZnCl_2$ solution | Treat 10 g of reagent grade Zn granules with 0.1 M HCl to remove any oxide coating. Clean the treated Zn granules with water and acetone. After dried up, 6.541 g of the Zn granules is weighed and dissolved in minimum amount of 5 M HCl by heating the solution to boil. Dilute the solution into a 1000-mL flask with de-ionized water. |
| 0.0100 M standard $Cu(NO_3)_2$ solution | Rinse 10 g of pure electrolytic Cu metal with diluted $HNO_3$ solution. Dissolve 6.355 g of the cleansed Cu into 120 mL 0.1 M $HNO_3$. Dilute the solution into a 1000-mL flask with de-ionized water. |
| Mg-EDTA solution | Prepare approximately 0.05 M $MgCl_2$ and 0.05 M EDTA solutions. Pipette 25.00 mL of the $MgCl_2$ solution into a conical flask. Add 15 mL of water and 2 drops of Eriochrome Black T solution. Warm to 60°C and titrate with the EDTA titration until the solution turns from red to blue. Mix equivalent amounts of the $MgCl_2$ and EDTA solutions and store in a polyethylene bottle. |
| Cu-EDTA solution | Prepare approximately 0.05 M $CuSO_4$ and EDTA solutions. Pipette 25.00 mL of the $CuSO_4$ solution into a 250-mL conical flask. Add pH 10 ammoniacal buffer dropwise until the solution turns to blue and the precipitate has re-dissolved. Add 100 mL of de-ionized water. Add more pH buffer if the turbidity is present. Add a pinch of Murexide indicator powder and titrate with the EDTA solution. |
| pH 5 acetate buffer | Dissolve 27.3 g of reagent grade sodium acetate trihydrate ($NaC_2H_3O_2 \cdot 3H_2O$) in 60 mL of 1 M HCl solution. Dilute with de-ionized water into a 1-L volumetric flask. |
| pH 10 ammoniacal buffer | Dissolve 70 g of reagent grade $NH_4Cl$ in 570 mL of reagent grade concentrated ammonia water (28 to 30% $NH_3$). Dilute with de-ionized water into a 1-L volumetric flask. Store in a polyethylene bottle. |

pH 1–3 by adding dilute nitric acid or ammonia water under stirring. Add 15 mL of de-ionized water and add 2 drops of Xylenol Orange indicator. Titrate with standard EDTA to the endpoint (from red to yellow). The weight of bismuth ($W_{Bi}$) in the 250-mL volumetric flask can be calculated from the volume ($V_{EDTA}$) and concentration ($C_{EDTA}$) of the standard EDTA used in the titration:

$$W_{Bi}(\text{mg}) = C_{EDTA}(\text{M}) \times V_{EDTA}(\text{mL}) \times \text{Molar mass of Bi} \times 10 \qquad (35)$$

*Interferences:* Alkaline earth metals and most divalent transition metals are masked in this pH range and do not interfere with the titration. The major interference metal ions are Fe(III), Th(IV), Cu(II), Sb(III), Hg(II), and Ti(IV). Aluminum ion in large amount also interferes with the titration. Ascorbic acid can mask Fe(III) and Hg(II) by reducing them to Fe(II) and Hg, respectively. Hydrazine can reduce Cu(II) to Cu(I). Sulfate masks Th(IV) and Ti(IV). Tartrate masks Sb(III). Aluminum can be masked by fluoride.

*Remarks:* Fe(III), Cu(II), Hg(II), Th(IV), Tl(III), and Sc(III) can be also titrated by this procedure. Other metal-ion indicators, including PAN, Pyrocatechol Violet, Cu-PAN, and Murexide, are used for the procedure as well.

## 10.2 Determination of Zn: DIRECT TITRATION AT pH 10

*Procedure:* Prepare the sample into a 250-mL volumetric flask. Pipette a 25.00-mL aliquot into a 250-mL conical flask. If the solution is acidic, add 1 M of NaOH dropwise under stirring until the solution approaches neutrality. Monitor pH with a pH meter. Add 15 mL of water, 5 mL of pH 10 ammoniacal buffer, and 2 drops of Eriochrome Black T immediately prior to the titration. Titrate with standardized EDTA to the endpoint (from red to blue). The weight of zinc ($W_{Zn}$) in the 250-mL volumetric flask can be calculated from the volume ($V_{EDTA}$) and concentration ($C_{EDTA}$) of the standard EDTA used in the titration:

$$W_{Zn}(\text{mg}) = C_{EDTA}(\text{M}) \times V_{EDTA}(\text{mL}) \times \text{Molar mass of Zn} \times 10 \qquad (36)$$

*Interferences:* Many metal ions can interfere with the titration. Masking is an effective method to screen the interference metals. For example, tartrate masks Fe(III), Al, Sb (III), and Sn(IV); 2-mercaptoethanol masks Hg(II), Cu(II), Pd(II), Pb, Cd, and Tl(III). Fluoride masks Al, Ba, Be, Ca, Sr, Fe(III) (in small amount), Mg, rare earths, Ti(IV), and Zr(IV). Ascorbic acid reduces Cu(II). Citrate masks Al, Sn(II), Th(IV), and Zr (IV). Carbonate masks U(IV).

*Remarks:* Many metal ions can be determined by this procedure with little or no modifications. Several metal-ion indicators are available for this procedure. If Eriochrome Black T (red to blue), Calmagite (red to blue), or Pyrocatechol Violet (violet to blue) is used as the indicator, cadmium can be determined by the procedure. Magnesium can be determined when the sample is heated to >50°C to increase the formation rate of Mg-EDTA complex. Calcium, barium, and even strontium can be determined if Mg-EDTA is added. Lead and indium(III) can be titrated if sufficient

tartrate is added to prevent hydroxide formation. Rare earths can be titrated by adding sufficient tartrate or citrate and boiling the solution. Manganese(II) can be determined if some ascorbic acid or hydroxylamine is added to prevent its oxidation and hydroxide formation.

As Cu(II), Ni, and Co form with Eriochrome Black T strong complexes that are too stable to be decomposed by EDTA, Murexide is a suitable indicator for the titration of these metal ions. Nickel can be directly titrated with the procedure. Cobalt can be determined when sufficient acetate is added. Copper can also be titrated by the procedure, but too much ammoniacal buffer is avoided because Cu-$NH_3$ complex is rather stable. If alkaline earths and Pb are determined by this procedure, cyanide is an effective agent to mask Cd, Co, Cu(II), Hg(II), Ni, Pd(II), Pt(II), Zn, and other transition metals.

## 10.3 Determination of Co: BACK TITRATION AT pH 5–6

*Procedure:* Dilute the sample into a 250-mL volumetric flask. Pipette a 25.00-mL aliquot into a 250-mL conical flask. Add excess amount of standard EDTA. Neutralize the solution with NaOH under stirring; use a pH meter to monitor pH. Add 5 mL of acetate buffer and heat the solution to boiling. Add 2 drops of PAN solution and titrate with standard $CuSO_4$ until the solution turns from blue to red-violet. The weight of Co can be calculated from the volumes and concentrations of the standard EDTA and $CuSO_4$ solutions.

$$W_{\mathrm{Co}}(\mathrm{mg}) = [C_{\mathrm{EDTA}}(\mathrm{M}) \times V_{\mathrm{EDTA}}(\mathrm{mL}) - C_{\mathrm{CuSO4}}(\mathrm{M}) \times V_{\mathrm{CuSO4}}(\mathrm{mL})] \times \text{Molar mass of Co} \times 10 \tag{37}$$

*Interferences:* Interferences from various metals can be eliminated by the addition of masking agents before neutralizing the solution. Ascorbic acid can mask Cr(III), Tl (III), Ti(IV), Fe(III), and Hg(II). Fluoride can mask Al, rare earths, and alkaline earths. Citrate masks Al, Sn(II), Th(IV), and Zr(IV). Pyrophosphate masks Cr(III) and Fe (III). Tartrate masks Sb(III), Sn(IV), and Zr(IV). Triethanolamine masks Al, Fe(III), Sn(IV), and Ti(IV).

*Remarks:* Metal ions such as Co, Ni, Fe(III), V(IV), Cu(II), Hg(II), Pb, Zn, Mn, rare earths, Al, Ga(III), and In(III) can be determined by this procedure. It is necessary to boil the solution because many metal ions form EDTA complexes at a slow rate, and Cu-PAN indicator functions properly at elevated temperature. Vanadium(IV) can be determined in the presence of ascorbic acid. As to Al, the sample solution should be boiled for 15 minutes to make sure that Al is completely transferred into its EDTA complex.

## 10.4 Determination of Ca AND Mg: SEQUENTIAL TITRATION

*Procedure:* Dilute the sample into a 250-mL volumetric flask. Pipette a 25.00-mL portion into a 250-mL conical flask. Add 3 drops of a 1% polyvinyl alcohol solution

and adjust the solution over pH 12.5 with KOH. Add 15 mL of de-ionized water, and add 5% of KCN and heat the solution to 60°C. Add 2 drops of Calcon indicator (1-(2-hydroxy-1-naphthylazo-2-naphthol-4-suphonic acid in 4 w/v% methanol). Titrate with standard EDTA to the endpoint (from red to blue). The calcium content is determined.

$$W_{\mathrm{Ca}}(\mathrm{mg}) = C_{\mathrm{EDTA}}(\mathrm{M}) \times V_{\mathrm{EDTA}}(\mathrm{mL}) \times \text{Molar mass of Ca} \times 10 \tag{38}$$

Add 5 mL of pH 10 ammoniacal buffer. Boil the solution until magnesium hydroxide dissolves. The solution turns back to red again because of the Mg-Calcon complex. Add 1 drop of Eriochrome Black T and titrate the solution with standard EDTA to the endpoint (from red to blue). This determines the content of magnesium.

$$W_{\mathrm{Mg}}(\mathrm{mg}) = C_{\mathrm{EDTA}}(\mathrm{M}) \times V_{\mathrm{EDTA}}(\mathrm{mL}) \times \text{Molar mass of Mg} \times 10 \tag{39}$$

*Remarks:* The polyvinyl alcohol reduces the adsorption of Calcon on the surface of $Mg(OH)_2$ precipitate[43]. Cyanide is used to mask Ag, Cd, Co, Cu(II), Fe(II), Hg(II), Ni, Pd(II), Pt(II), and Zn. Interferences from Cu(II), Fe(II), Au(III), Co, Ni, Cd, and Zn can be also masked by fluoride. Fe(III), Al, Ti(IV), and Sn(IV) can be masked by triethanolamine.

## 10.5 Determination of Phosphate Anion: Indirect Titration

*Procedure:* Dilute the phosphate sample into a 250-mL volumetric flask. Pipette a 25.00-mL aliquot into a 250-mL beaker, and add 50-mL of de-ionized water. Add 1 mL of concentrated HCl solution, a few drops of methyl red, and excess amount of $MgCl_2$ solution. Heat the solution to boiling. Add concentrated ammonia water dropwise under vigorous stirring until methyl red turns from red to yellow. Further add a few more milliliters and allow standing for 2 hours. $MgNH_4PO_4{\cdot}6H_2O$ crystalline precipitate forms. Filter through a sintered glass crucible (porosity G4) and wash thoroughly with 1 M ammoniacal solution.

Rinse the 250-mL beaker with 25 mL of hot 1 M HCl solution. Pour the solution into the glass crucible to dissolve the precipitate and wash into a 500-mL conical flask. Wash the beaker and the crucible with further 10 mL of HCl solution and 50 mL of de-ionized water. Add a measured excess of standard EDTA. Neutralize the solution with 1 M NaOH. Add 5 mL of pH 10 ammoniacal buffer and a few drops of Eriochrome Black T. Warm the solution to 60°C and back-titrate the excess EDTA with a standard $MgCl_2$ solution. The weight of phosphate in the 250-mL sample can be determined by the difference of the amount of standard EDTA and the amount of the standard $MgCl_2$ used in the back titration:

$$\begin{aligned} W_{\mathrm{Phosphate}}(\mathrm{mg}) = {} & [C_{\mathrm{EDTA}}(\mathrm{M}) \times V_{\mathrm{EDTA}}(\mathrm{mL}) - C_{\mathrm{Mg}}(\mathrm{M}) \times V_{\mathrm{Mg}}(\mathrm{mL})] \\ & \times \text{Molar mass of } PO_4^{3-} \times 10 \end{aligned} \tag{40}$$

*Remarks:* Trace amount of heavy-metal ions can be co-precipitated with $MgNH_4PO_4 \cdot 6H_2O$. As many of these metals can block the indicator, they should be masked with proper agents. For example, tartrate can be used to mask Fe, Mn, Al, and Cu. Cyanide can be added to mask Cu(II), Ag, Cd, Co, Fe(III), Fe(II), Hg(II), Ni, Pd(II), Pt(II), and Zn. Tartrate should be added when the solution is acidic. Cyanide should be added after the solution is neutralized. Safety tools such as masks and gloves should be prepared when cyanide is used.

## 10.6 Determination of Al, Pb(II), AND Zn: SEQUENTIAL TITRATION

*Procedure:* Dilute the sample into a 250-mL volumetric flask. Pipette a 25.00-mL aliquot into a 300-mL conical flask, and dilute to 100 mL with de-ionized water. Add excess amount of standard EDTA and 0.1 g of ascorbic acid. Boil the solution for 1 minute. To this solution 25 mL of 20% KCN solution was added, and immediately, 10 mL of concentrated ammonium hydroxide was added to prevent the formation of HCN and adjust the medium at pH 10. Gloves and masks must be used as a precaution when working with KCN. Add a few drops of Eriochrome Black T solution. The solution is cooled to 10°C in an ice bath for the rest of the procedure. Titrate the excess EDTA with standard $MnSO_4$ to the endpoint (from blue to red).

To determine Al, add 20 mL of triethanolamine and 5 mL of hydroxyl amine 10% (w/v) to the above solution and boil the solution for 1 minute. Add a few drops of Eriochrome Black T solution and titrate the liberated EDTA with standard $MnSO_4$ to the endpoint (from blue to red). The amount of Al in the sample can be determined by:

$$W_{\mathrm{Al}}(\mathrm{mg}) = C_{\mathrm{EDTA}}(\mathrm{M}) \times V_{\mathrm{EDTA}}(\mathrm{mL}) \times \text{Molar mass of Al} \times 10 \qquad (41)$$

After the titration of Al, 5 mL of 20% alcoholic solution of 2,3-dimercaptopropanol is added with slow stirring. Lead(II) is masked from the EDTA, and the liberated EDTA is titrated with $MnSO_4$ using Eriochrome Black T to the endpoint (from blue to red). The amount of Pb(II) can be determined by:

$$W_{\mathrm{Pb}}(\mathrm{mg}) = C_{\mathrm{EDTA}}(\mathrm{M}) \times V_{\mathrm{EDTA}}(\mathrm{mL}) \times \text{Molar mass of Pb} \times 10 \qquad (42)$$

Finally, zinc is quantitatively de-masked from its cyanide complex by the addition of (3:1) 20 g of 4% formaldehyde: acetone solution. The liberated Zn is titrated with standard EDTA at pH 10 using Eriochrome Black T to the endpoint (from red to blue). After titration, the addition of the formaldehyde:acetone mixture is repeated, followed by a second titration, until the solution no longer turned red. The total amount of EDTA used can be used to determine the amount of Zn in the sample:

$$W_{\mathrm{Zn}}(\mathrm{mg}) = C_{\mathrm{EDTA}}(\mathrm{M}) \times V_{\mathrm{EDTA}}(\mathrm{mL}) \times \text{Molar mass of Zn} \times 10 \qquad (43)$$

*Remarks:* This process is designed to sequentially determine Al, Pb(II), and Zn in glass and glass frit samples, which contain small amounts of Ca and Mg, and trace amounts of Fe, Cu, Mn, Co, Ni, Ti, and Zr. Ascorbic acid and cyanide are added to reduce Fe(III), Cu(II), and Mn(VII)/(IV) and mask Fe(II), Mn(II), Cr, Co, Ni, and Ti. EDTA is added to mask Al, Pb(II), and Zn together with Zr, Ca, and Mg. Then, the Al is de-masked with triethanolamine and the released EDTA is titrated at pH 10. Lead is de-masked with 2,3-dimercaptopropanol and the liberated EDTA is titrated. Then, zinc is de-masked by adding formaldehyde/acetone solution and titrated by standard EDTA. As all the titrations are carried out at pH with $MnSO_4$, the solution is cooled to 10°C, at which Mg and Ca will not interfere. More detailed information about this process can be found in the literature [44].

## 10.7 Determination of Fe(III), Cd, AND Mg: SEQUENTIAL TITRATION

*Procedure:* Dilute the sample into a 250-mL volumetric flask. Pipette a 25.00-mL aliquot into a 500-mL conical flask. Add excess amount of standard EDTA. Neutralize with NaOH while stirring with a magnetic bar. Monitor pH with a pH meter. Add 5 mL of pH 5 acetate buffer and add 2 drops of PAN indicator solution. Back-titrate the solution with standard $CuSO_4$ to the endpoint (from yellow to red). The amount of Fe (III) and Cd is obtained. To the same solution, add 5.00 mL of pH 10 ammoniacal buffer. Titrate with EDTA until the solution turns back to yellow. This determines the amount of Mg.

$$W_{\mathrm{Mg}}(\mathrm{mg}) = C_{\mathrm{EDTA}}(\mathrm{M}) \times V_{\mathrm{EDTA}}(\mathrm{mL}) \times \text{Molar mass of Mg} \times 10 \tag{44}$$

Then, add 10 mL of 5% KCN solution, following with 5.00 mL of concentrated ammonium hydroxide solution. Conduct this operation in a fume hood. Prepare gloves and masks in case of accidents. Cyanide will replace EDTA from its complex with cadmium. Add 2 drops of Eriochrome Black T and titrate with standard $MgNO_3$ until the solution turns from blue to red. The result determines the amount of Cd.

$$W_{\mathrm{Cd}}(\mathrm{mg}) = C_{\mathrm{Mg}}(\mathrm{M}) \times V_{\mathrm{Mg}}(\mathrm{mL}) \times \text{Molar mass of Cd} \times 10 \tag{45}$$

The amount of Fe can be calculated from the difference between the results of the back titration and replacement titration.

$$\begin{aligned} W_{\mathrm{Fe}}(\mathrm{mg}) = {} & [C_{\mathrm{EDTA}}(\mathrm{M}) \times V_{\mathrm{EDTA}}(\mathrm{mL}) - C_{\mathrm{CuSO4}}(\mathrm{M}) \\ & \times V_{\mathrm{CuSO4}}(\mathrm{mL}) - C_{\mathrm{Mg}}(\mathrm{M}) \times V_{\mathrm{Mg}}(\mathrm{mL})] \times \text{Molar mass of Fe} \times 10 \end{aligned} \tag{46}$$

*Remarks:* Many sequential EDTA titrations have been developed and are available in literature. It is noticed there are numerous possibilities of combining pH-adjustment,

masking/de-masking schemes, titration procedures, and endpoint detection methods to achieve the goal of the determination of multiple metal ions in a sample solution. If a new titration approach is to be designed for an analytical task, steps for achieving a successful procedure may be generalized as the following:

1. Inspect the stability constants of the EDTA complexes for the metal ions to be determined. List the titration procedures and conditions (pH range and endpoint detection methods) for each single metal ion to be determined. The tables included in this chapter are helpful for obtaining such information. Table 1 lists the stability constants of the EDTA complexes for common metal ions. Table 3 lists the properties and applications of some metal-ion indicators. Tables 5 and 6 list the direct and back titrations for a number of metal ions. More data and information can be found in the literature as well.
2. pH-adjustment should always be the first to be considered as an effective means of sequential titration if the stability constants of the metal-EDTA complexes are significantly different from each other. If the stability constants of the metal-EDTA complexes are close to each other, masking/de-masking approaches will be considered. Furthermore, elegant procedures for the determination of multiple metal ions with close properties can be achieved by combining different types of titration procedures (direct, back-, and indirect titrations) with masking schemes. Table 7 lists common masking agents and their applications in EDTA titrations.
3. It is noted that a sequential titration with one aliquot of sample is not always successful if multiple metal-ion indicators or masking agents are necessary. A satisfactory sequential titration normally uses one or two metal-ion indicators. If more than two indicators are necessary for the titrations, the titrations may be conducted in more than one aliquot. Bear in mind that metal-ion indicators are not always good choices for EDTA titrations. Sometimes, other detection methods can dramatically simplify the process. A good example is the use of a potentiometric titration to determine Bi(III), Cu(II), and Ca in a single portion of the sample. A mercury electrode permits a sequential titration of these three metals by adjusting the medium at pH 1, 5, and 10. Ion-selective electrodes (ISEs) can also provide good endpoint detections for many metals if the titration is conducted in the proper pH range for ISE. Table 4 lists some common ISEs with basic specifications. In some cases, when the sample is so complicated that no masking/de-masking scheme works properly, chemical separation procedures have to be considered.

# Electronic Circular Dichroism Spectroscopy

**Ferenc Zsila M.D., Ph.D.**
*Chemical Research Center, Institute of Biomolecular Chemistry, Budapest, Hungary*

## 1 INTRODUCTION

### 1.1 Definitions and Abbreviations Used in the Chapter

***1.1.1 Definitions*** *Anisotropy factor (termed also as Kuhn's dissymmetry ratio or g factor)*: It is a dimensionless parameter expressing a ratio of the strength of CD to strength of light absorption of the chiral sample at specific wavelengths. $g = \Delta A/A = \Delta\varepsilon/\varepsilon$, where $\Delta A$ is the difference of the absorption of the sample against left- and right-circularly polarized light beams ($A_L - A_R$). It is a useful parameter of how difficult it is to measure the CD in the region of a given absorption band, because $\Delta A/A$ is proportional to the signal/noise ratio where $\Delta A$ determines the signal and $A$ determines the noise. The anisotropy factor is rarely larger than $10^{-2}$ and more commonly is around $10^{-4}$. $g$ factor can be used as analytical tool to characterize the diastereomeric and enantiomeric purities of optically active materials.

*Chiral exciton coupling*: It is based on the through space exciton interaction between two or more chirally oriented chromophores which are not conjugated to each other and show strong ($\varepsilon \geq 10^4$) $\pi \rightarrow \pi^*$ type absorption. Coupling of the $\pi \rightarrow \pi^*$ transition moments in a symmetric and anti-symmetric fashion gives rise to a

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing,*

CD band pair of mutually opposite signs in the region of the absorption peak (bisignate CD spectrum). The exciton coupling may occur intra- or intermolecularly, it may be degenerate (between identical chromophores), or non-degenerate (between different chromophores).

*Chiroptical ("chiral optical") spectroscopy*: It covers various spectroscopy techniques which measure differences in the interaction of chiral molecules with left- and right-circularly polarized light. These techniques include: electronic circular dichroism (CD or ECD), synchrotron radiation circular dichroism, vibrational circular dichroism, fluorescence-detected circular dichroism, circularly polarized luminescence, and vibrational Raman optical activity.

*Chromophore*: A molecule (e.g., benzoic acid) or a molecular subgroup (e.g., the polyene chain of amphotericine B) that gives rise to absorption of electromagnetic radiation of specified wavelengths. The term is equally used in the context of electronic transitions in the ultraviolet ($\lambda < 350$ nm) and in the visible spectral region.

*Circular dichroism*: CD is the difference in absorption of left- and right-circularly polarized light beams passed through an optically active (chiral) medium: $\Delta A = A_L - A_R$. In molar units: $\Delta\varepsilon = \varepsilon_L - \varepsilon_R$, where $\Delta\varepsilon$ is the molar circular dichroic absorption coefficient in $M^{-1}\,cm^{-1}$.

*Circularly polarized light (cpl)*: In cpl the electric field vector remains constant in magnitude, but traces out a helix as a function of time. It rotates in a clockwise (right) or in an anti-clockwise (left) sense (rcpl, lcpl). The vector summation of in-phase rcpl and lcpl results in plane polarized light.

*Cotton effect (CE)*: Positive or negative bands in the CD spectrum associated with light absorption bands of chromophoric groups of the sample compound. Stereochemical information of the analyte are encoded in the number, sign, magnitude, width, and spectral position of CEs.

*Ellipticity ($\Theta$)*: Due to the interaction with a chiral compound, the electric field vector of the light traces out an elliptical path after passing through the sample. The angle of the ellipsoidally polarized transmitted light is defined as the ellipticity angle ($\Theta$). The ellipticity of a chiral molecule is directly proportional to $\Delta A$. Due to historical reasons, most CD spectropolarimeters produce CD spectra in units of in millidegrees (mdeg) versus wavelength (nm) although they directly measure differential absorbance values ($\Delta A$). The relationship between $\Theta$ and $\Delta A$ is $\Delta A = 4\pi\Theta$ (degrees)/180ln10 $= \Theta$(mdeg)/32982.

*Enantiomeric purity (e.p.) or enantiomeric excess (e.e.)*: It means the excess (in per cent) of one enantiomer over the other: if $\%R > \%S$ then e.e.$\% = \%R - \%S$ and e.e.$\% = \%S - \%R$ if $\%R < \%S$. For instance, a 75%:25% mixture of *R*- and *S*-enantiomers has a $75\% - 25\% = 50\%$ e.e. Enantiomeric purity relates directly to the CD signal because if there is no enantiomeric excess (50%*R*:50%*S*) then there is no CD signal.

*Extrinsic circular dichroism: see Induced circular dichroism*

*g Factor: see Anisotropy factor*

*Induced (extrinsic) circular dichroism (ICD)*: Achiral molecules can acquire CD activity through binding to asymmetric hosts such as proteins, nucleic acids, cyclodextrines. The ICD bands are shown in the light absorption region of the guest

and their sign and magnitude are crucially dependent on the binding geometry as well as on the chromophore interaction energy with the host matrix.

*Intrinsic circular dichroism*: CD activity caused by genuine disymmetry of chiral entities. Most frequently, it is associated with the presence of asymmetric centers in the molecule.

*Mean residue (or residual) ellipticity ($[\Theta]_{MRW}$)*: For far-UV CD spectra (190–240 nm) of proteins and peptides, CD data are routinely normalized by scaling to the repeating unit of the polymer. Because essentially every residue in a protein is associated with a peptide bond, spectra in this region can be directly compared by using the peptide bond as the repeating unit. CD data are expressed in terms of the mean residue weight (MRW), which is defined by $\mathrm{MRW} = M/(N-1)$, where $M$ is the molecular mass of the polypeptide chain in daltons and $N$ is the number of amino acids, so the value of $N-1$ gives the number of peptide bonds. The mean residue ellipticity is given by the equation of

$$[\Theta]_{\mathrm{MRW}} = \mathrm{MRW} \times \Theta/10 \times c \times l$$

where $\Theta$ is the observed ellipticity (in mdeg), $c$ is the concentration (mg/mL), and $l$ is the optical path length (cm). The dimensions of $[\Theta]_{\mathrm{MRW}}$ is deg cm$^2$/dmol, and the quantity is independent of molecular weight.

*Molar circular dichroic absorption coefficient ($\Delta\varepsilon$ in $M^{-1}\,cm^{-1}$)*: It is the difference of the molar absorption coefficients ($\varepsilon_{\mathrm{L}}$ and $\varepsilon_{\mathrm{R}}$) of the chiral solute: $\Delta A = A_{\mathrm{L}} - A_{\mathrm{R}} = \varepsilon_{\mathrm{L}} \times c \times l - \varepsilon_{\mathrm{R}} \times c \times l = \Delta\varepsilon \times c \times l \Leftrightarrow \Delta\varepsilon = \varepsilon_{\mathrm{L}} - \varepsilon_{\mathrm{R}}$, where $c$ is the molar concentration (M) and $l$ is the optical path length (cm).

*Molar ellipticity ($[\Theta]$)*: While $\Delta\varepsilon$ (or $\Delta A$) is the preferred way to express CD values, authors frequently report data as molar ellipticity $[\Theta]$ in deg cm$^2$/dmol: $[\Theta] = \Theta/10 \times c \times l$ where $\Theta$ is the observed ellipticity (in mdeg), $c$ is the molar concentration (M), and $l$ is the optical path length (cm). Molar ellipticity and molar circular dichroic absorption are related by the expression $[\Theta] = 3298 \times \Delta\varepsilon$.

*Optical activity*: The ability of chiral chemical compounds to rotate the plane of polarization of plane polarized light, an effect that results from the difference in refractive indices lcpl and rcpl components of the plane polarized light.

*Plane polarized light*: A transverse light wave of which electric and magnetic field vectors oscillate in single planes perpendicular to each other. Its polarization is defined by the direction of the electric field. Plane polarized light can be decomposed into two, left- and right-circularly polarized components of opposite helicity but identical frequency, speed, and intensity.

## 1.2 Basic Features of Electronic Circular Dichroism Spectroscopy

ECD or CD is the manifestation of the important property of chiral compounds to absorb lcpl and rcpl to different extents. CD spectroscopy is closely related to the conventional UV/VIS absorption spectrophotometry, a well-known and routinely applied technique in the broad fields of pharmaceutical sciences [1–3]. Mutual comparison of principal features of the two spectroscopic techniques can be useful for understanding the basic nature of the CD method (Table 1).

The CD instrument generates lcpl and rcpl which are passed alternately through the sample. There is no absorption difference for achiral molecules against lcpl and rcpl ($A_L = A_R$, $\Delta A = 0$). Conversely, unpolarized light used in UV/VIS spectrophotometers is unsuitable for discrimination of enantiomers due to their identical absorption. However, lcpl and rcpl do interact differently with optically active materials resulting in a small but measurable difference in the light absorption of the sample. The absorption difference is expressed conventionally as $\Delta A = A_L - A_R$ or $\Delta\varepsilon = \varepsilon_L - \varepsilon_R$ and is plotted in the function of the wavelength. Accordingly, CD bands can be positive ($A_L > A_R$) or negative ($A_L < A_R$). Importantly, CD bands (called also Cotton effects, CE) can only be measured where absorption bands are present. If chiral molecules do not show optical absorbance (e.g., carbohydrates, ethambutol above 200 nm), their CD signal will be zero in spite of the presence of asymmetric centers.

Sign, shape, number, intensity, and wavelength position of CEs in the CD spectrum and their changes under different experimental conditions carry a wealth of valuable structural information on the compound under study.

**TABLE 1 Comparison of Principal Features of UV/VIS Absorption and CD Spectroscopy**

| | UV/VIS Absorption Spectroscopy | CD Spectroscopy |
|---|---|---|
| Type of compounds can be studied | Chiral and achiral | Only chiral |
| Type of the detector used | Photomultiplier | Photomultiplier |
| Polarization of the electromagnetic radiation | Unpolarized | Circularly polarized |
| Wavelength range of the electromagnetic radiation | 180–800 nm | 180–800 nm |
| Type of transitions detected | Electronic excitations ($\pi \rightarrow \pi^*$, $n \rightarrow \pi^*$) | Chirally perturbed electronic excitations ($\pi \rightarrow \pi^*$, $n \rightarrow \pi^*$) |
| Relative strength of the signals measured | 1 $A$ unit | $10^{-3} - 10^{-5}$ $\Delta A$ unit |
| Mode of data acquisition | $A$ values in the function of wavelength | $\Delta A$ (and $A$) values in the function of wavelength |
| Sign of the bands in the spectrum | Always positive ($A > 0$) | Positive or negative ($0 > \Delta A$ or $\Delta A > 0$) |
| Spectra of pure enantiomers | Identical curves | Mirror-image curves |
| Validity of the Beer's law | Valid | Valid |
| Molar units used | $\varepsilon$ ($M^{-1}\,cm^{-1}$) | $\Delta\varepsilon$ ($M^{-1}\,cm^{-1}$) |

Discussion of the theoretical basis of CD spectroscopy is beyond the scope of this chapter. For in-depth treatments, readers are referred to several excellent books [1,4–15] and review papers [16–28].

## 1.3 CD Instrumentation

CD instruments are available from several manufacturers including Jasco Inc. (http://www.jascoinc.com), Aviv Biomedical Inc. (http://www.avivbiomedical.com), and Applied Photophysics (http://www.photophysics.com).

CD bands are most commonly measured in the UV and VIS regions of the spectrum from 170–180 to 700–800 nm.

The CD signal ($\Delta A$) is of the order of $\pm 10^{-5}$ to $\pm 10^{-3}$ for usual samples corresponding to an ellipticity ($\Theta$) of $\approx \pm 0.3$ to $\pm 30$ mdeg, so that highly sensitive instrumentation is required for its accurate measurement. Due to historical reasons, most CD spectropolarimeters display CD spectra in units of ellipticity ($\Theta$), in millidegrees against wavelength (nm) although they directly measure $\Delta A$ values. The relationship between $\Theta$ and $\Delta A$ is $\Delta A = \Theta(\text{millidegrees})/32982$. Chiroptical data for small organic/inorganic molecules are usually expressed in $\Delta\varepsilon$, units while CD data of biopolymers are often given in ellipticity values ($\Theta$ or $[\Theta]$).

Most commercial CD equipments are single beam and use the modulation technique [15,17,29,30]. First, unpolarized monochromatic light is linearly polarized and then passes through a photoelastic modulator (PEM), a piezoelectric device which produces lcpl and rcpl alternately, with a switching frequency of typically 50 kHz. For optically inactive samples absorption of the two beams is equal and the output current

generated in the detector is constant. In chiral samples, the absorption of the lcpl and rcpl will be different so the light intensity seen by the photomultiplier will also be modulated at the same frequency. The larger direct current component of the detector is characteristic to the total light absorption of the sample, whereas the small alternating current component relates to the CD of the sample and is directly proportional to $\Delta A$. Thus, beside CD spectra CD instruments record simultaneously UV/VIS absorption curves as well.

Single beam CD spectropolarimeters should be calibrated regularly, at least monthly if the machine is in regular use, using a standard sample with known absorbance and CD value [11,17]. The most frequently used standard for CD calibration is the D-( + )-10-camphorsulfonic acid.

A new double beam instrument from OLIS Inc. (On-Line Instrument Systems, Inc., http://www.olisweb.com) has recently been introduced on the market, which uses direct substraction of lcpl and rcpl for obtaining the CD signal [15,30]. The instrument utilizes two modulated cpl beams out of phase by 180° which pass separately through different parts of one cuvette and detected simultaneously by two detectors. So, absorption of lcpl and rcpl is measured directly. Since each beam is a reference for the other, this technique has some advantages. For instance, energy fluctuations of the light source are eliminated since they affect both beams equally. In addition, this system needs no calibration and results in zero drift over time and nearly flat baselines. However, the two beams pass through different parts of the sample. So, it is particularly important to prepare homogenous and particle-free sample solution, to use high-quality quartz cuvettes with no intrinsic strain, and to clean cuvettes regularly to avoid buildup of hard-to-remove organic and inorganic deposits.

The high-energy light sources used in CD machines (150–450 W xenon arc lamp, water, or air cooled) generate ozone during operation. Thus, a supply of high-purity, dry nitrogen gas is essential to purge oxygen in order to avoid degradation of the optics by ozone, as well as to decrease background optical absorbance of $O_2$ in the sample chamber for performing measurements below 200 nm [17].

A Peltier system for temperature control and thermal ramping is an invaluable accessory, particularly for studies of the thermal unfolding of proteins/nucleic acids, and for thermodynamic and kinetic investigations of ligand–biopolymer interactions.

## 1.4 Conditions for Employing CD Spectroscopy

***1.4.1 Light Absorption and Stereochemical Requirements of CD Spectroscopic Investigations*** Sample must contain one or more chromophore showing light in the wavelength range where CD equipments operate.

Chromophores must be associated with a chiral environment. Here, "association" means

- connection of the chromophore to chiral center(s) via one or more covalent bonds;

OR

- non-covalent association of the chromophoric moiety to an asymmetric (chiral) host (e.g., proteins, DNA/RNA, cyclodextrins, etc.).

In spite of the lack of any stereocenter, a small group of chromophores are themselves chiral (inherent chirality). Their mirror images are not superimposable with each other, since their structures devoid of either a center or a plane of symmetry. Such type of chromophores (hexahelicene, twisted biphenyls) exhibit pronounced CD activity [16].

It is important the total absorbance (cell and sample solution combined) to be kept in the analytical range between 0.2 and 1.2 AU [11,30]. The maximum absorbance of the sample tolerated in CD experiments can be about 2 AU. An absorbance of 0.4–1.0 AU gives the optimal signal-to-noise (S/N) ratio.

***1.4.2 Chemical Nature of Materials Suitable for CD Spectroscopic Studies*** Chiral organic/inorganic compounds, organometallics [9,12,13]; peptides, polypeptides, proteins [9,10]; natural and synthetic oligo- and polynucleotides [9,10]; mono-, oligo-, and polysaccharides [10]; synthetic chiral polymers [31,32].

***1.4.3 Physical Forms of the Sample Material Suitable for CD Measurements*** Dissolved in organic or in aqueous solvents (most frequent); liquids; vapor phase [33]; crystalline/semicrystalline phases (solid state CD) [34]; liquid crystals [20]; thin films [35].

***1.4.4 Solvents for CD Spectroscopic Measurements*** Organic and aqueous solvents used in CD spectroscopic investigations must be optically inactive and have the lowest possible absorbance in the spectral region scanned. Organic solvents should be of spectroscopic purity and should be checked for the absence of absorbing impurities.

Distilled water is particularly transparent solvent but buffer additives (phosphate, chloride, nitrate, borate, MOPS, EDTA, SDS, etc.) can significantly increase light absorption below 230 nm [11,36,37].

Since oxygen absorbs light below 200 nm, solvents should be degassed before measuring in that spectral region.

Due to the single-beam construction of most CD instruments, sample CD spectra must always be corrected by subtracting a baseline spectrum of the cell plus blank solvent obtained under identical acquisition conditions.

## 1.5 Advantageous and Disadvantageous Features of Circular Dichroism Spectroscopy

Advantages

- CD spectroscopy provides instant answer for structural problems qualitative in hand: discrimination between enantiomers and diastereomers (Fig. 1) by simple comparison of their CD spectra, detection of chirality of biopolymers (e.g. B or Z conformations of DNA), demonstration of drug–biopolymer (e.g., drug–protein, drug–nucleic acid, drug–cyclodextrin) and biopolymer–biopolymer (e.g., protein–protein, protein–DNA) binding interactions [38].
- Molecules can be studied under simulative physiological conditions, i.e., pH 7.4 aqueous buffer systems, 37°C.

***FIGURE 1*** *Comparison of CD spectra of the angiotensin converting enzyme inhibitor captopril (1-[(2S) 3-mercapto-2-methylpropionyl]-(S)-proline) and its stereoisomers measured in deionized water. Note the mirror-image CD curves of the enantiomers and the spectral differences caused by inverted chirality of the side-chain or the ring stereocenter. Adapted and modified from Ref. [28].*

- CD spectra can be taken under a wide range of experimental conditions (concentration, pH, temperature, ionic strength, detergents, etc.) [39,40].
- CD spectroscopy is a non-destructive technique. If necessary, sample materials can be restored after measurements.
- CD instruments record two kinds of experimental data simultaneously; the CD and the UV/VIS absorption spectrum of the sample. The absorption curve is essential for proper interpretation of the CD data and it often provides further information on the compound under study [21,41,42]. In addition, the ratio of the dichroic/absorbance signal ($\Delta A/A$, $g$ factor) is a valuable analytical tool for determination of enantiomeric composition of chiral pharmaceuticals (see Sections 2.1.2 and 2.1.3).
- CD spectra of multi-component samples can be recorded and studied without previous analytical separation [14,43–45]. Since optically inactive compounds give no CD contribution, they do not disturb CD signals of the chiral component. Chiral but optically transparent molecules (e.g., mono-, oligo-, and polysaccharides) do not interfere by CD bands of chiral substances above 210 nm. CD investigation of mixtures of chiral substances showing separate CD bands above 200 nm is also possible.
- In contrast to other physical methods such as NMR and mass-spectrometry, CD spectroscopic characterization of glycoproteins and membrane proteins can be

performed without rigorous pre-treatment of the samples since neither carbohydrate moieties nor residual lipids disturb CD signals of the protein component.

- Recording of CD spectra is quick and can be completed within 15–30 min [37]. In practice, a single protein far-UV CD spectrum over the 190–240 nm range can take as little as ≈3 min. In addition, only small quantities of protein are required for measuring far-UV CD spectra (200 μl of a 1 to 10 μM solution in a rectangular cell with 0.1 cm pathlength). Titration experiments (e.g., ligand–protein, DNA–protein binding), temperature-dependent measurements need more time, usually 1–2 h [39,46,47]. CD and UV absorbance detection at a fixed wavelength have been used in a high throughput HPLC flow through assay to distinguish between enantiomers of 1-phenylethanol with a throughput of 700–900 assays per day [48].
- Since the electronic transitions between the ground and excited states occurs on a very short time scale ($\sim 10^{-15}$ s), a wide range of biologically important processes can be time resolved by CD spectroscopy.
- Using stopped-flow CD equipment makes possible to study structural changes in proteins which occur in a few tens of milliseconds timescale [49,50].

Limitations and pitfalls

- Samples must be optically active. Achiral compounds cannot be studied by CD spectroscopy.
- Chiral centers and the chromophores can mutually be located in a manner (separated from each other by unhindered single bonds, e.g., thyroxine, dihydrofolate) that produces only a very weak or no measurable CD activity [43,51,52].
- Conventional CD spectroscopic investigation of chiral molecules showing light absorption only below 200 nm is difficult (e.g., mono- and disaccharides). At wavelengths less than 200 nm such compounds often have incompletely developed CD spectra, not reaching a maximum signal. In addition, most organic solvents and buffers show limited optical transparency below 200 nm even by using shorther path length cuvettes (1 mm and below).
- Compared to NMR and X-ray crystallography methods, CD spectroscopy provides only low-resolution structural information both for small molecules and biopolymers [17,53,54]. For instance, secondary structure of proteins (λ-helix, β-sheet content) can be estimated from CD data but CD spectra are not able to provide detailed information such as which regions of the protein have what structure, what are the shape, and amino acid composition of ligand binding pockets and clefts.
- Relatively large amounts of proteins (typically ≈1–2 mg) are required for measuring near-UV CD spectra (240–320 nm) and for conducting ligand–protein CD titration studies [17,40].
- Limits of direct CD measurements made on bulk samples using direct transmission detection are similar to those for absorbance, approximately 1 μM for a 1 cm path length.

- Compounds having absorption bands below cut-off point of the solvent applied cannot be studied by CD spectroscopy due to the low intensity of the light reaching the detector. This problem arises when the sample compound is insoluble in other, optically transparent solvents.
- Materials with strong fluorescence or phosphorescence might cause artifacts in the CD spectrum due to the significant number of emitted photons reaching the detector [55].
- Samples containing colloidal particles (liposomes, molecular aggregates, membrane fragments) might cause differential light absorption and light-scattering effects resulting in optical artifacts in CD and absorption spectra [5,56,57]. These problems can be offset to some extent by adjustment of cuvette path length, but they remain a significant limitation.
- Membrane proteins should be solubilized for CD measurements to eliminate optical artifacts. However, different detergents may lead to the alteration of the native protein structure which will be seen in the CD spectra [58–60].

## 1.6 Main Application Fields of CD Spectroscopy

### *1.6.1 Stereochemical Characterization of Organic and Inorganic Compounds*

- Determination of the absolute configuration of molecules by using empirical and non-empirical methods. Conformational analysis of chiral molecules with known absolute configuration [7,9,12–14,16,18,19,26,28,61,62].

There are numerous reports on CD spectroscopic investigation of stereochemistry of chiral pharmaceutical agents. Since the main purpose of this chapter to summarize the practical aspects of CD spectroscopy most relevant for the pharmaceutical industry, its application in configurational, and conformational analysis of organic/inorganic compounds is not covered here. Readers who are interested in specific details are referred to Table 2 where selected examples of therapeutic drugs studied by CD spectroscopy are shown [25,41,51,63–95].

### *1.6.2 Structural Characterization of Biopolymers*

- Estimation of secondary (proteins/peptides) [10,54,96–98] and characterization of tertiary structure of proteins [49,96] under various experimental conditions.
- Determination of thermodynamics and kinetics of folding/unfolding of proteins and peptides.
- Characterization of protein/peptide aggregations [10,30].
- Determination of conformation and conformational transitions of nucleic acids [10,30,99].
- Evaluation of conformation of carbohydrates [10].

**TABLE 2 Examples for CD Spectroscopic Studies of Stereochemistry of Various Pharmaceutical Agents**

| Drug | Ref. |
|---|---|
| Anthracycline antibiotics | [63] |
| Antibiotics | [64–68] |
| Barbiturates | [69] |
| Benzodiazepines | [70,71] |
| Bradykinin | [72] |
| $Ca^{2+}$ antagonists | [73] |
| Captopril | [25] |
| Cinchona alkaloids | [74] |
| Codeine derivatives | [75] |
| Colchicine | [76,77] |
| Ketamine | [41] |
| Methotrexate | [78] |
| NSAIDs | [51,79,80] |
| Nicotine | [81] |
| Ouabain | [82] |
| Prostacyclins | [83] |
| Riboflavin | [84] |
| Steroid hormones | [85,86] |
| Strychnine alkaloids | [87] |
| Taxol | [88] |
| Tolperisone | [89] |
| Vasopressin | [90] |
| *Vinca* alkaloids | [91–93] |
| Vitamin $B_{12}$ | [94] |
| Warfarin | [95] |

### 1.6.3 Investigation of Biopolymer–Biopolymer Interactions

- Detection and characterization of protein–protein [10,100], protein–peptide, protein/peptide–nucleic acid [10,47], and protein/peptide–carbohydrate [101] binding interactions.
- Estimation of the binding constant, stoichiometry, thermodynamics, and kinetics of binding [21,27,40].

### 1.6.4 Investigation of Ligand–Biopolymer Interactions

- Detection and characterization of ligand–protein binding interactions (e.g., drug–receptor [102], substrate/inhibitor–enzyme [103,104], co-enzyme–enzyme [27,105], drug–plasma protein [21,106]).
- Determination of binding constant/stoichiometry [107,108], mechanism, thermodynamics, and kinetics of binding.
- Characterization of the binding environment. Detection of protein conformational changes upon ligand binding [9,30,109].

- Detection and characterization of ligand–nucleic acid binding interactions [27,109]. Determination of binding mode (intercalation, groove binding), estimation of binding constant/stoichiometry [110], thermodynamics, and kinetics of binding.
- Detection and characterization of ligand–polysaccharide binding interactions [27,111].

#### *1.6.5 Analytical Applications*

- Determination of concentration and enantiomeric purity of chiral drugs in pharmaceutical dosage forms by direct CD spectroscopic measurements or by a CD detector coupled with HPLC system [14,44,112].

## 2 PRACTICAL APPLICATIONS OF CD SPECTROSCOPY IN PHARMACEUTICAL SCIENCES

### 2.1 Analytical Applications

#### *2.1.1 Drug Determination by CD Spectroscopic Method in Pharmaceutical Preparations and in Biological Samples*

##### *2.1.1.1 Direct CD Spectroscopic Determination of Chiral Drugs in Pharmaceutical Formulations*

*Summary* Due to the high-selectivity of CD spectroscopy for molecular chirality, this technique can efficiently be used for the identification and direct quantitative determination of chiral drugs in pharmaceutical preparations, even in the simultaneous presence of several kinds of additives. Such assays can be performed without prolonged workup including pre-concentration, derivatization, or various separation steps.

*Selected Examples* A quick and simple CD method has been elaborated for chiroptical determination of 15 cephalosporins in commercial oral suspensions, injections, and capsules [65]. Based on the discriminative CD spectral features of pure forms, the antibiotics were classified into five groups. Using CD spectroscopic data measured at different concentrations, calibration graphs have been constructed for each drug for the purpose of quantitative analysis. The limit of quantitation (LOQ) was found to be 5 μg/mL. Subsequent measurement of CD spectra of commercial samples dissolved in distilled water without performing any derivatization, filtration, or separation steps allowed correct determination of antibiotic levels of these preparations.

Penicillin V and cephalothin contents of laboratory mixtures containing lactose, starch, and caffeine have successfully been determined by exploiting distinctive features of CD spectra of that antibiotics [113].

Based on the large difference between CD spectra of tetracycline and its epimer 4-epitetracycline, a simple and sensitive CD assay has been presented for quantitative determination of the epimers in commercial tetracycline capsules [66].

Feasibility of the CD detection method has been demonstrated by estimation of water-soluble vitamin contents of pharmaceutical and food preparations [43]. Quantified amounts of commercial vitamin tablets and juice products were directly dissolved in or diluted with buffer + EDTA solution and then CD spectra were taken and compared to the reference curves of pure ascorbic acid and riboflavin.

Quick and easily reproducible CD method for quantitative determination of heroin in illicit materials has been reported [114]. Among the procedures tested, best results were obtained for direct CD determination of heroin at 253 nm as a morphine formed in the sample after basic hydrolysis. This step significantly enhanced the limit of detection (LOD) since the positive UV CD maximum of morphine is seven times higher than that of heroin.

CD spectroscopy might be useful in direct determination of two or more chiral drugs being present simultaneously in the same preparation. A simple protocol, which requires no separation or sample pre-treatment steps has been developed for direct quantification of cocaine and morphine [115]. Though both drugs are chiral and display partly overlapping CEs, their simultaneous CD investigation is still possible by measuring and analyzing CD data pairs of the mixture and of either components at pre-selected wavelength pairs.

Subtle differences in CD spectra of structurally related compounds can be used for diagnostic purposes, as it has been demonstrated by identification and quantitative determination of various opiates in binary and ternary mixtures including morphine, codeine, thebaine, and noscapine [116].

*Comments*

- Depending on the stereochemistry, CD signal of some chiral drugs may be so weak that makes possible only qualitative analysis.
- Achiral molecules showing UV/VIS absorption bands interfere to the extent that their absorption lowers the S/N ratio and limits the level of detection. Natural dyes and coloring agents added to pharmaceuticals are among the worst interferences.

#### *2.1.1.2 Direct CD Spectroscopic Determination of Chiral Drugs in Biological Fluids*

*Summary and Comments* Direct determination of CD active chiral drugs in serum or plasma is possible only if the compounds show CD bands above 300–330 nm, where intrinsic CD contribution of major plasma proteins (albumin, immunoglobulins) is negligible. For chiroptical study of drugs in serum showing CEs only between 240 and 300 nm, protein removal is needed for the elimination of strong masking effect of near-UV protein CD bands.

*Selected Examples* Protein precipitation had to be performed prior to the quantitative CD determination of β-lactam antibiotics in serum samples [117]. Positive and negative CD bands of ceftriaxone, cephalothin, and cephalexin were

measured between 240 and 290 nm in protein-free serum at different drug concentrations. Validity and accuracy of the method was confirmed by using the model drug cefoxitin, cefuroxime, and cefotaxime.

Direct estimation of optically active antibiotics such as ampicillin, cefoxitin, and cephalexin has been performed by CD method in voided urine of patients, excreting different amounts of proteins, under multiple drug administration [118]. To simulate protein CD contribution of the samples obtained from subjects showing proteinuria, human serum albumin (HSA) was used as the analytical standard for the correction of CD spectra. The validation procedure demonstrated that CD values followed the Beer's law and were linear relation to drug concentration in the range of $\approx 10^{-6} - 10^{-4}$ M.

Direct analysis of tetracycline in human urine has also been described using CD spectroscopy [119]. By measuring amplitude of the strong positive CE at 295 nm, the LOD was found to be $4 \times 10^{-6}$ M.

#### *2.1.1.3 Indirect CD Spectroscopic Identification and Determination of Drugs by Chirality Induction*

*Summary* Achiral drugs and racemic mixtures cannot be studied directly by CD spectroscopy. It is conceivable that such compounds can be made "visible" for the CD detector and can be quantitated if an extrinsic/induced CD signal is generated upon inclusion of the drug chromophore into asymmetric environment of a chiral host. Cyclodextrines (CyDs) are well-known chiral complexation agents showing no CD activity above 210–220 nm. Inclusion of drug molecules into CyD cavity can result in solute-induced CD band(s) which can be used for drug identification and determination [120,121]. The procedure is simple: an aliquot of standardized CyD stock solution has to be added to the sample solution prior to CD measurement. It can be applied for achiral drugs [120], racemic mixtures, and even for chiral compounds. In the latter case, intrinsic CD curve of the enantiomerically pure guest is altered upon CyD complexation [122].

Drug content of pharmaceutical preparations might be assayed without prior mixture separation.

*Selected Examples* Distinctive features of CD spectra of 10 therapeutic benzodiazepines induced by β-CyD have been described [123]. Total drug concentration of commercial tablets and capsules containing diazepam and flurazepam has been determined directly by measuring ICD bands after addition of β-CyD to the sample solution. No time-consuming separation procedure was necessary for the CD assays of which reproducibility were better than 0.2%.

Meperidine (achiral) content of commercially available tablets was directly assayed using ICD data ($\Delta\varepsilon_{max}$ at 271 nm) obtained for a simple solution of tablets prepared in alkaline β-CyD ($10^{-2}$ M) stock reagent [121]. Correspondence with the prescribed amount was better than 98%.

ICD data have been used to estimate the association constants of eight barbiturate-CyD complexes [124]. The association constant obtained for seconal then was used

for quantitative assays of the drug in commercial seconal sodium suppositories without prior mixture separation.

*Comments*

- In order to determine drug concentration from ICD values, formation constant of drug-CyD complex must be known. This can be estimated from series of spectroscopic data obtained by measuring ICD values at different host/guest molar ratios.
- For working with racemic drugs, pure enantiomers are needed for determining stability constants.
- Achiral additives of pharmaceutical preparations bearing chromophoric groups (e.g., procaine, lidocaine, benzoic acid, caffeine) might also be included in the CyD cavity generating additional extrinsic CD bands which can be mixed to ICD bands of the drug under study.
- See also the Comments in Section 2.2.1 (Drug–Cyclodextrin Complexes).

### 2.1.2 Purity Investigation of Chiral Pharmaceutical Compounds by CD Spectroscopy

*2.1.2.1 Summary* Unfortunately, the literature of direct CD spectrometric purity investigations of drug substances and preparations is very short. Between the reasons could be found the high cost of a CD spectropolarimeter, the instruments, and methods with highest performance and sensitivity than the chiroptical methods and the limited possibility of use. On the other hand, the chiroptical methods have intrinsic selectivity in the analysis of chiral compounds. The most widely spread techniques are the different kinds of separation methods. The chiroptical aspects of separation techniques are detailed in Section 2.1.3, the unique and rare examples, which do not apply separation, are collected here.

Chiral pharmaceutical compounds could contain achiral and chiral impurities. In the mixtures containing achiral substances the chiroptical methods are selective and specific for the chiral components. The chiral impurities could be sorted in two groups:

1. Molecules with similar structure (structure isomers, homologs)
2. Stereoisomers (diastereomers, enantiomers)

*2.1.2.2 Selected Examples in Group 1* In this group the steroids have largest pharmaceutical impact. For instance, ethynodiol is manufactured from norethisterone, so norethisterone acetate might always remain as impurity in the product ethynodiol diacetate. The norethisterone has selective wavelengths over 331 nm due to the chiraly perturbed $\Delta^4$-3-keto chromophore, and in this way 0.5–5% of impurities could be selectively determined [125]. Similar problem is the $\Delta^5$-ethisterone determination in ethisterone [126]. Quick and accurate direct and indirect CD spectroscopic methods

were developed for the simultaneous determination of ethisterone (17α-ethinyl-17-hydroxy-4-androstene-3-one) and its $\Delta^5$-isomer ($\Delta^5$-ethisterone). The direct method is based on the selective negative CE of the $\Delta^4$-3-oxo group in ethisterone (negative maximum at 348 nm in dioxane) and measurement of the ellipticity at 296 nm (positive maximum of $\Delta^5$-ethisterone), where the measured ellipticity is the sum of those of the two isomers. In the indirect procedure $\Delta^5$-ethisterone was transformed to ethisterone by base catalyzed isomerization and the ellipticities were measured at 339 nm in ethanol before and after isomerization.

Drug molecules, like 6-oxo morphinane derivatives and 3-keto-steroids due to the $n \rightarrow \pi^*$ electronic transition (270–350 nm) can be measured directly with high precisity and selectivity [127]. The oxim formation reaction of keton group with hydroxil-amine is a short and quantitative reaction and causes dramatic change in the CD spectrum. The difference CD spectroscopy gives further sensitivity and selectivity to the method eliminating interference from other chiral compounds in pharmaceutical products. In addition to the improved selectivity, a further advantage of the method suggested is the high sensitivity since the 6-oxo-morphinans studied can be determined at a concentration of 1 mg/mL this procedure can certainly be applied to the analysis of biological fluids. The method based on the use of difference CD spectra might have an important role in the field of illicit drug analysis.

The quantitative determination of $\Delta^4$-3-ketosteroids is based on the considerable difference between the ellipticities before and after oxime formation around 320 nm [128]. The difference ellipticity for the six ketosteroids examined varies linearly with the concentration in the interval $6 \times 10^{-6} - 3 \times 10^{-3}$ mol/L. The advantages of the determination of $\Delta^4$-3- ketosteroids by difference CD spectroscopy are improved selectivity and high sensitivity. This method can be applied to the determination of $\Delta^4$-3-ketosteroids in the presence of achiral compounds and those chiral substances, which do not react with hydroxylamine hydrochloride. The progestogen norgestimate can be contaminated with levonorgestrel acetate. The reference [128] demonstrates that 0.02% $\Delta^4$-3-ketosteroid contamination in norgestimate can be determined with required accuracy by the difference CD spectroscopic method.

*2.1.2.3 Selected Examples in Group 2* Erskine *et al.* [129] elaborated a method for the determination of e.p. using CD and UV spectroscopy for ephedrine and mandelic acid enantiomers and ephedrine–pseudo-ephedrine mixtures. The CD and UV spectra overlap each other in the investigated region (256–280 nm). The CD and UV data were collected at 0.1 nm interval and the results were calculated by the partial least squares method. The UV spectral data give information about the total concentration of the sample, while the sign and intensity of the chiroptical signal provide information about enantiomeric composition and the enantiomeric excess.

The enantiomeric composition of phenylglycine and mandelic acid was successfully determined by the application of the anisotropy factor ($g$ factor) derivable from the ratio of the CD and the absorbance signals ($g = \Delta A/A$) [130]. This is an intensive, concentration-independent physico-chemical parameter, which eliminates concen-

tration-related errors caused by sample preparation, dilution, and so on. For the two enantiomers, it has the same numerical value with opposite signs, and is therefore a function of the enantiomeric composition. The procedure based on the determination of the $g$ factor is rapid, accurate, and eminently suitable for routine quality control purposes enabling the determination to be carried out with an accuracy of 0.1%. Only one restriction factor must be considered: if any kind of contamination (chiral or achiral) distorts the CD or UV signal, it must be separated.

Complex formation can be used as an aid to improve the sensitivity of the determination of e.p. of compounds; for instance, in the case of ethambutol complexation with copper(II) was used for this purpose [131]. A method based also on complex formation has been developed for determination of the binary mixtures of pseudoephedrine and ephedrine using chiral Cu(II)–tartrate complexes as derivatizing agents [132]. The reaction is a simple ligand exchange between tartrate and the chiral drug and results in a shift of the wavelength of CD detection to the visible range. The CD spectral change is proportional to the concentration of D-pseudoephedrine and at 527 nm the L-pseudoephedrine complexes have an isobestic point. At this wavelength, the D-pseudoephedrine content can be determined. The effects are entirely opposite if L-tartrate is changed to D-tartrate in which case the D-pseudoephedrine complexes will produce the isobestic point and the L-pseudoephedrine content can be determined. The detection limit for the enantiomeric impurity was in the order of 2%.

A specific complex formation of the anti-inflammatory drug (±)-ketoprofen with bovine serum albumin (BSA) was investigated [79]. The CE arising from the $n \rightarrow \pi^*$ transition of ketoprofen shows magnification due to the protein binding and it can be used to measure the e.p. of (−)-ketoprofen with excellent precision.

Separation and purification of drug enantiomers (thiopental, pentobarbital, methadone) by chiral capillary electrophoresis was supported by CD spectroscopic characterization of the enantiomeric composition of the collected fractions [133,134]. The samples were prepared by chiral recycling isotachophoresis of a racemic mixture.

A method has been elaborated for the determination of enantiomeric purity of amphetamine samples [135]. The procedure is based on the derivatization of amphetamine with 2,4-dinitrofluorobenzene and subsequent measurement of the anisotropy factor by dual (CD/UV) spectroscopy. The advantage of the derivatization is that due to the bathochromic shift, more selective and sensitive analysis can be performed than it would be possible in the underivatized form. Both ellipticity and absorbance values were in linear relation to the concentration in the range of $5 \times 10^{-6} - 6 \times 10^{-4}$ mol/L. By investigating binary mixtures of amphetamine enantiomers containing 63.3–98.8% of (+)-amphetamine the accuracy of the determination of e.p. was found to be 0.2–0.3%.

### 2.1.3 Coupled HPLC-CD Techniques for Solving Pharmaceutical Problems

*2.1.3.1 Advantages and Limitations of CD Detectors* The detectors (UV, fluorescence, refractive index (RI), electrochemical) generally used in the

analytical practice cannot detect chiral properties of investigated molecules and cannot differentiate between the enantiomers directly. The identification of enantiomers and the detection of chiral properties could be carried out with chiroptical detectors only.

There are two types of chiroptical detectors basically: the polarimetric (optical rotatory dispersion (ORD)) and CD equipments. The ORD detectors which is based upon RI differences between rcpl and lcpl can detect all kind of chiral compounds, but the sensitivity and selectivity of the method is not high enough as required in pharmaceutical industry. The sensitivity of CD detectors exceed the sensitivity of ORD, but the presence of chiral or chirally perturbed cromophore is required in the sample. This restriction limits the range of investigated materials, but gives inherent selectivity to the method. The sensitivity of CD detectors exceeds the sensitivity of ORD and RI devices, but equal or less sensitive as the UV detectors. Further problem is the relatively high cost and the limited wavelength scale. The shortest wavelength is 220 nm, typically, which could be used in the case of highly transparent eluent. The noise increases below 240 nm significantly, if the eluent contains slightly transparent component.

The most important aspect in method development for CD detection is the $g$ factor. The CD detector measures $\Delta A$, but measures the sum of absorptivity ($A$) of the cpl components also. The low value of $\Delta A/A$ ($\Delta\varepsilon/\varepsilon$) ratio limits the possibilities. If $\Delta A$ is too low, it manifests in low CD signal while if $A$ is too high, the compound cannot be detected with the precisity required by pharmaceutical industry, due to the poor S/N ratio. Additional limitation could be arisen from low $\Delta A$ values: to increase the measured CD signal, concentration of the sample must be increased, but the injected quantity is limited by the column loadability.

In spite of these limitations, the CD detection could be used at several fields of pharmaceutical analysis. The representative applications are as follows:

1. Characterization of optical and geometrical isomers after separation and quantitative determination of chiral compounds (Section 2.1.3.1)
2. Determination of e.p. after chiral or achiral separations (Section 2.1.3.2)

### *2.1.3.2 HPLC-CD Detection of Chiral Pharmaceuticals*

***Summary and Comments*** The analytical scale separation of isomers or different chiral substances allows on-line chiroptical characterization with CD detector and there is no need to purchase preparative columns and collect the fractions for posterior process of the collected samples. This method is especially important in cases when a dynamic equilibrium persists between the isomers and the time scale is relatively short, but exceed the separation time.

In time mode when CD detection occurs at a fixed wavelength, the elution order of isomers could be determined while the stop-flow method or the fast spectrum registration mode enables to register CD spectra of eluted components. If HPLC-CD systems are operated in fixed wavelength mode, stereochemical information carried by the complete CD spectrum cannot not be utilized. The sign of the measured

CD signal is variable, depending upon the wavelength selected, and cannot be correlated with the absolute stereochemistry of the analyte.

The construction of CD equipments allow the parallel detection of the CD and UV signals. This technical feature bears specific application possibilities. In practice, the CD spectropolarimeter itself can be directly used as a CD detector by coupling it with an HPLC system. A novel, and much more economic solution is the use of a CD detector, designed specifically for HPLC measurements [136]. This detector is suitable to determine 99.8–98% e.e. values. Basic and general information about the HPLC-CD detection could be achieved from the literature [14,137–142].

*Selected Examples* The neuromuscular blocking agent atracurium besylate contains 10 isomers in various proportions as four racemic pairs and two meso compound and their *cis*- or *trans*-isomers. Directly coupled HPLC-NMR and HPLC-CD detectors were applied to the identification of the isomers. The HPLC-NMR method was used for identifying the isomeric configuration and the enantiomeric pairs. The HPLC-CD experiments were complementary in the determination of the absolute stereochemistry [143].

Takahashi et al. [144] investigated the warfarin and 7-hydroxywarfarin binding process to proteins and measured the enantiomers from plasma and urine. The serially coupled CD detection combined with stop-flow method supported the identification of isomers and allowed to register on-line CD spectra of eluted components.

A diazepam analog was synthetized, characterized and its stereospecific HSA binding properties were investigated by NMR, CD spectroscopy, and HPLC-CD methods. The on-line CD detection clearly demonstrated that the stereoselectivity of the compound on immobilized HSA stationary phase is opposite to all the other studied benzodiazepines [145].

The metabolism of lorazepam enantiomers was also studied from plasma by on-line CD detection [146].

The 2,3-benzodiazepine derivative tofisopam has two types of chirality: the C(5) atom generates central chirality, while the diazepine ring affects the existence of two helical conformers. The four isomers were separated on cellulose-based stationary phase and were detected by the coupled CD equipment. The on-line CD spectra of the peaks obtained by stop-flow method definitely showed different chiral character [147].

A non-nucleoside reverse transcriptase inhibitor chiral molecule (DPC 961) which is used in the treatment of HIV infection was investigated. The plasma extract was analyzed with coupled HPLC-CD method to determine, if racemization occurred during metabolism. The tandem detection method (CD/UV) confirmed that there was no racemization of the chiral center of DPC 961 during metabolism. The LOD of the CD detector for DPC 961 at 240 nm was approximately 5 ng injected on column while the LOD for the UV detector at 250 nm was approximately 0.2 ng under the same conditions [148].

Ethisterone is one of the classical synthetic progestogenes and it is an important intermediate in the synthesis of the diuretic and cardiac drug spironolactone. In the course of the synthesis, a large amount of the $\Delta^5$-isomer is also formed. The ratio

***FIGURE 2*** *HPLC-CD chromatogram of a sample containing 41.4% of ethisterone and 58.6% of $\Delta^5$-isomer before (continuous line) and after (dashed line) base-catalyzed isomerization. Inset: CD spectra of the reaction mixture of the isomerization reaction at different time intervals from start of the reaction up to the completion. (a) 0 min, (b) 2 min, (c) 4 min, (d) 6 min, (e) 8 min, (f) 12 min, (g) 25 min, (h) 35 min. The (g) and (h) curves correspond to the CD spectrum of pure ethisterone. Note the CD sign inversion at 297 nm. Adapted and modified from Ref. [126].*

of $\Delta^4$- and $\Delta^5$ isomers should be measured in the course of the in-process control during the spironolactone synthesis. Using HPLC-CD method (Fig. 2) it is possible to detect not only ethisterone with negative CE, but also the $\Delta^5$-isomer with low UV activity, and above all this, the base-catalyzed isomerization may be examined as well [126].

The application of HPLC-CD for identification of pharmacologically active compounds, such as dexamphetamine, 5-hydroxytryptophan, (−)-huperizine A, interferon as standards, in registered drugs, in falsifications, and in food supplements was described [149]. The UV, fluorescence, and CD detection were compared and validated for chromatographic monitoring of conformational properties of human interferon α2b [150].

The biologically important dehydroepiandrosterone (DHEA) is a precursor in the biological steroid synthesis, and it can be converted into other hormones. Gergely *et al.* [151] has developed an HPLC-CD method, where DHEA and three related biosynthetic steroids were separated. The use of CD detector provided selective detection because of its inherent selectivity for chiral compounds and it allowed the application of high detection wavelength (295 nm), presenting more selective detection with minimal background noise.

A specific scope of the dual CD and UV detection is the peak homogeneity monitoring. A general method is described in [152] and the feasibility of the method is exemplified by the analysis of partially overlapping codeine-hydrocodone and completely overlapping codeine-oxycodone samples. Another possibility for the peak homogeneity control is the fast CD spectrum recording during the separation process. Apparently homogeneous peaks of very similar analytes were analyzed and resolution was carried out [153].

CD detection combined with HPLC was used to demonstrate the chiral separation of perbenzoyl derivatives of the anti-tuberculosis agent ethambutol stereoisomers: the enantiomeric (−)-(*R*,*R*) and (+)-(*S*,*S*)-ethambutols together with the (*meso*)-(*R*,*S*)-form [154]. Comparison of the UV-HPLC and CD-HPLC traces showed that the first two UV peaks with equal and opposite CD effects correspond to the therapeutically active (+)-(*S*,*S*)-isomer (eutomer), and the inactive (−)-(*R*,*R*)-isomer (distomer) while the third peak could be seen only in the UV trace corresponds to the CD inactive *meso* form (Fig. 3). Derivatization was necessary since ethambutol lacks chromophoric groups and thus cannot be studied by CD spectroscopy. Upon derivatization, exciton type CD signals can be measured above 200 nm in the strong $\pi \rightarrow \pi^*$ UV band of the benzoyl moieties.

***FIGURE 3*** *HPLC-CD/UV chromatogram of perbenzoyl (R = COPh) derivatives of ethambutol (R = H) stereoisomers. The first and second peaks (CD and UV) correspond to the (+)-(S,S)- and the (−)-(R,R)-enantiomers. The third peak (UV only) represents the meso-form. Adapted and modified from Ref. [154].*

The absolute configurations of two novel and selective cyclooxygenase-2 inhibitors were assigned by the comparison of computed and experimental CD spectra measured on-line with HPLC-CD detection [155].

#### 2.1.3.3 Enantiomeric Purity Determination Using HPLC-CD System

*Summary and Comments* Resolution of enantiomers on chiral stationary phases is a commonplace recently. The chiroptical detection after chiral separation is preferred if the elution order of isomers is not known and if the sensitivity is acceptable. The opposite CD sign of enantiomers identifies them unambiguously. The restrictive features of the CD detection are the LOD and LOQ whose parameters vigorously depend on the $g$ factor. The $g$ value is not merely a restrictive factor, but it may be a useful analytical tool, also. As was previously mentioned, CD instruments detect and register simultaneously the CD ($\Delta A$) and UV ($A$) signal. The ratio of the $\Delta A/A$ for a single enantiomer is a constant value, the sign of the $g$ factor is identical as the sign of the CD signal and independent from the concentration. For details see Section 2.1.2.

By using the $g$ factor no chiral separation is needed and the e.e. can be determined from the chromatographic results of a non-chiral separation. The separation of other components showing own CD signal or UV absorbance is required, since these components distort $g$ values and cause erroneous purity determination. Additionally, the method is valid only if the $g$ factor is independent of concentration and if it is linear with respect to e.e. These conditions may not hold in the case of dimerization or self-association of the chiral analyte because own particular CD contribution of such enantiomeric or diastereomeric species would modify the CD profile of the monomeric form. Thus, it is mandatory to check this possibility in each new system under study.

Chiral analytes (e.g., sugars) showing no optical absorbance above 200 nm have to be made visible for the CD detector by previous derivatization step using chromophoric reactants.

*Selected Examples* A sensitive, selective, and versatile CD-based HPLC detection system was used for validation of the e.p. assay in the quality control of chiral drugs upon non-chiral stationary phases [156]. The precision and accuracy of the method were checked for selected samples showing values of the $g$ factor in the order of $10^{-1}$–$10^{-4}$. Very high accuracy was obtained in the case of extreme e.p. values (less than 1% or higher than 99% e.p.) and also for a low $g$ value ($2 \times 10^{-4}$) compound. Plots of $g$ values as a function of e.p. showed good linearity for all analytes, with correlation coefficients ($r^2$) between 0.970 and 0.999, even in the range of extreme e.p. values. The high selectivity of this detection system allows a selective monitoring of analytes in complex mixtures and makes the baseline stable. The minimum detectable e.p. value is mainly related to the maximum $g$ value, while the minimum amount of the detectable analyte depends on the values of the CD and absorption signals.

A simple and rapid non-enantioselective HPLC method using a CD detector for the determination of the e.p. of dexchlorpheniramine maleate was developed [157]. Such

a method, which does not require the enantiomer separation, seems to ensure adequate performance; indeed the results obtained and the reported data on precision, linearity and sensitivity show that the described HPLC-CD system is suitable for the determination of e.p. of compounds having an unfavorable CD signal.

The HPLC determination of efaroxan e.p. was successfully performed by using a $C_8$ silica column and a CD detector [136]. This method presents the advantages of being fast and precise and does not require the use of an expensive chiral column. Moreover, due to UV and CD detections, it was possible to simultaneously determine the optical and chemical purities of drugs. This last feature could be applied to study racemization and metabolization of the eutomer in biological fluids, too. For the first time, this HPLC method—with achiral support and CD detection—has been fully validated according to the ICH (International Conference on Harmonization) criteria and can replace the classical HPLC approach—chiral support and UV detection. Nevertheless, the LOQ in terms of e.p. is for the moment too high (98%) compared with results generally obtained with UV detection. Some technical improvements concerning the sensitivity and the linearity of the CD detector are required in the near future to achieve quantification of e.p. up to 99.8% level.

A specific, inexpensive optics were inserted into a conventional photo-diode array detector and this modification resulted in a multi-beam CD detector. With this equipment the e.p. determination of malic acid in beverages was performed [158]. The samples whose e.p. were lower than 97.3% were classified as adulterated and it was confirmed by capillary electrophoresis. Some of these samples were labeled as 100% pure natural product and no additives was listed in their ingredients. In this context, the HPLC-CD detection is a feasible method to explore falsifications in natural products.

Using non-chiral HPLC coupled with a CD detector, a new method was developed to determine the e.p. of glucose [159]. Due to the lack of chromophores absorbing light above 200 nm, the sugar molecules were derivatized with *p*-bromobenzoyl chloride that made CD detection possible in the UV region. In order to achieve more accurate e.p. determination the wavelength of detection was set at 254 nm, near to the maximum difference of *g* factors of D- and L-glucose derivatives. The method is suitable for microscale analysis of glycoside and saccharide. As an application, the component glucose of a glucan was assayed to be pure D-isomer.

The HPLC-CD approach can be used for the development of fast enantiopurity assays in support of high throughput pharmaceutical process research investigations, e.g., for monitoring e.p. of products of asymmetric catalysis [48,55]. The HPLC flow injection analysis (FIA) combined with UV and CD detection results in FIA chromatograms (Fig. 4) which can be visually interpreted, allowing the user to rapidly assess which samples are showing conversion to product, which are forming the desired enantiomer, and allowing an immediate rough estimate of e.p. [55]

Holik and Mannschreck [160] discussed the possible errors determining e.p. from overlapping (non-resolved) HPLC peaks, while Gergely *et al.* [161] reported further practical information, how unbiased *g* factor can be calculated from the chromatographic data.

***FIGURE 4*** *Flow injection HPLC-CD analysis of mixtures of a compound of varying degrees of enantiopurity. Duplicate injections of samples prepared by mixing solutions of the individual enantiomers, nominally 95% e.e. (R), 57% e.e. (R); 0% e.e., 57% e.e. (S), 95% e.e (S). Note that 10 measurements were taken within 4.5 min. Adapted and modified from Ref. [55].*

## 2.2 Using CD Spectroscopy for Characterization of Pharmaceutical Preparations

### *2.2.1 Drug–Cyclodextrin Complexes*

*2.2.1.1 Summary* α-, β-, and γ-cyclodextrins (CyD) and their derivatives have been used extensively by the pharmaceutical industry, especially for enhancing the solubility, stability, and bioavailability of drug molecules [120,162]. These cyclic sugar hosts formed by the degradation of starch possess a hydrophilic surface and a hydrophobic internal cavity suitable for complexation of a wide variety of pharmaceutical agents. Due to the presence of numerous stereogenic centers (e.g., 35 in β-CyD) inclusion of achiral guest compounds in the asymmetric cavity might induce CEs in the CD spectrum of guest compounds [121,162,163] (Fig. 5A). For enantiomers of racemic mixtures, the resulted complexes are in diastereomeric relation of which non-equivalent chiroptical contributions result in non-zero CD activity [164,165] (Fig. 5B). CyD complexation of pure enantiomers might also be detected due to the modification of their intrinsic CD profile in relation to that measured in CyD-free solution [166–169] (Fig. 5C). It should be noted that simultaneous inclusion of two guest molecules is also possible especially for CyDs with large cavity (γ-CyD). In such cases, mutual chiral disposition of the entrapped guest chromophores dictated by the asymmetric host might result in guest–guest chiral intermolecular exciton coupling and characteristic ICD band splitting [170–173].

Chiroptical investigation of drug–CyD complexes can be useful to resolve several kinds of pharmaceutically relevant issues.

- CyD complexation of achiral/racemic or chiral drugs can be quickly demonstrated by measuring extrinsic or modified intrinsic CD bands of the guest compounds [162,167,168,174,175].

***FIGURE 5*** *(a) Representation of CD spectra ($\lambda > 210$ nm) of a CyD and an achiral guest before and after the formation of the inclusion complex. (b) CD spectra of a CyD and a racemic mixture before and after the formation of inclusion complexes being in diastereomeric relation. (c) CD spectra of a CyD and a chiral guest showing intrinsic CD bands before and after the formation of the inclusion complex. Adapted and modified from Ref. [162].*

- Concentration dependence of the CD signals allows to estimate binding parameters of the inclusion complexes. From series of CD spectroscopic data obtained by increasing guest concentration in sample solution of CyD kept at fixed concentration (or vice versa), the equilibrium constant and the stoichiometry of the complexes can be calculated [162,169,176].

- The presence/absence of ICD bands of achiral/racemic compounds or the alteration of intrinsic CD signals of chiral agents can serve as spectroscopic tool for screening of different CyDs to pre-select hosts with promising inclusion capability for selected drug molecules [177,178].
- Monitoring the change of ICD spectra of drug–CyD complexes under various experimental conditions (pH, temperature, time, ionic strength, additives, etc.) allows the characterization of physico-chemical stability and optimal conditions of formation of the inclusion complexes [162,168,177,179,180].
- Sign, shape, and intensity of extrinsic CEs of drug–CyD complexes are structure-dependent and can thus be used to assess the geometrical arrangement of guest compounds inside the CyD cavity [162,163,175].

*2.2.1.2 Selected Examples* Formation of CyD inclusion complexes of numerous pharmaceutical substances were demonstrated by measuring extrinsic CD spectra. In Table 3, some representative examples are shown with binding parameters estimated from analysis of ICD data [123,124,165,167,174,175,177,181–185].

The antipsychotic agent ziprasidone was formulated by using β-CyD sulfobutyl ether for solubilization of the drug. ICD spectra of various salt forms of ziprasidone suggested that the counterion of each salt form participates in the complex formation [166]. The ICD values at 318 nm measured at different guest:host molar ratios indicated 1:1 stoichiometric relationship.

Far-UV CD spectra of the bradykinin potentiating pentapeptide complexed with β-CyD qualitatively demonstrated the host:guest interaction [166]. CD curve of the peptide characteristic for the random coil structure changed drastically in the presence of β-CyD suggesting greater conformational rigidity within the complex.

Alteration of the intrinsic CD spectrum of luteinizing hormone-releasing hormone agonist buserelin acetate indicated that the aromatic side chains of the peptide are incorporated into the hydrophobic cavity of dimethyl-β-CyD [186].

**TABLE 3 Examples for Drug–CyD Interactions Studied by CD Spectroscopy**

| Drug | CyD | Stoichiometry [drug]:[CyD] | $K_a$ ($M^{-1}$) | Ref. |
|---|---|---|---|---|
| Barbiturates | β | 1:1 | $0.2–5.5 \times 10^2$ | [124] |
| Benzodiazepines | β | 1:1 | $1.1–9.3 \times 10^2$ | [123] |
| Diflunisal | β | 1:1 | $1.7 \times 10^3$ | [181] |
| Diclofenac | β | 1:1 | $3.5 \times 10^2$ | [182] |
| Dicoumarol | β | 1:1 | $4.9 \times 10^3$ | [175] |
| Doxorubicin | γ | 1:1 | $6.7 \times 10^2$ | [177] |
| Ephedrine | β | 1:1 | $1.8 \times 10^2$ | [183] |
| Flufenamic acid | β | 1:1 | $1.3 \times 10^3$ | [167] |
| Hydrocortisone | α, β, γ, dimethyl-β | 1:1 | $1.7–6.0 \times 10^3$ | [184] |
| Licochalcone-A | β | 1:1 | $3.2 \times 10^2$ | [174] |
| (±)-Metoprolol | α, β, HP-β | 1:1 | $0.6–3.5 \times 10^2$ | [165] |
| Zileuton enantiomers | β, γ | 1:1 | $0.7–5.1 \times 10^3$ | [185] |

Association constant and stoichiometry values were estimated from ICD titration data.

#### 2.2.1.3 Comments

- CyDs are optically transparent above 210–220 nm and they have no contribution either to the CD or the absorption spectra. For CD spectral analysis below 220 nm where intrinsic CEs of CyDs can be observed, chiroptical contribution of CyDs must always be taken into consideration by arithmetic subtraction of CD curve of free CyD from that of the guest–CyD complexes.
- Small molecule–CyD complexation does not necessarily result in CD spectral changes [184,187]. This might be due to various reasons, such as inclusion of the non-chromophoric part of the guest, and sterically rigid chiral molecules of which intrinsic CD signals are not or hardly affected upon the inclusion [163].
- There is no correlation between the value of the binding constant of guest–CyD complexes and the intensity of the ICD bands. In spite of a high constant, ICD amplitudes may be small and vice versa [163,184].
- Interpretation of ICD spectra may be difficult when the guest molecule contains more than one chromophore. The CD bands induced by different chiral environments of the chromophores might overlap resulting unusual CD profile which can only be resolved by using additional information obtained with monochromophoric guests [188].
- In some cases, especially when guest molecules have high conformational flexibility, measure of the CD spectral changes induced by CyDs might not correlate with the stability constants estimated by other methods [189].
- Depending on the concentration used, CyDs can form aggregates [190]. In most cases, size of these aggregates remains small (<20 nm) and does not affect optical properties of the sample but in some cases they can grow causing significant light scattering and thus distorted CD spectra.
- CyD associates can also act as solubilizers binding of drugs through non-inclusion manner [184,191]. In such cases, care must be taken in interpreting and using ICD data since they can reflect both inclusion and non-inclusion interactions, respectively.

### 2.2.2 Protein and Peptide Pharmaceuticals

*2.2.2.1 Summary* CD spectroscopy is a sensitive and straightforward tool for elucidation solution structure of peptides and proteins under variety of experimental conditions. In the far-UV region of the spectrum (190–240 nm), CD bands of proteins arise from the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions of peptide bonds and aromatic chromophores and report on the basic elements of secondary structure (e.g., α-helix, β-sheet) [10,192,193]. The near-UV CD spectrum (240–320 nm) is determined by asymmetric environment of the aromatic side chains of Trp, Tyr, Phe, and by the chirality of disulfide bonds [194,195]. CD signals of this region are highly dependent on the tertiary structure of the protein. Evaluation of the far-UV and near-UV CD curves enables

- to verify the correct folding and final conformation of a protein;
- quantitative assessment of the secondary structure elements (λ-helix, β-sheet content);

- to test changes of biologically active conformation of proteins under different conditions (e.g., effect of temperature, pH, freeze-thawing cycles, additives, derivatization) [196–199];
- to follow structural changes during formulation, storage, release, and administration (degradation, folding/unfolding, self-association/dissociation) [200–202];
- to investigate the structural equivalency of mutant/native [203], recombinant/native [204], and recombinant/recombinant therapeutic proteins;
- to check impurities of protein samples (e.g., DNA).

*2.2.2.2 Selected Examples* Far-UV and near-UV CD curves of a monoclonal antibody were measured and compared before and after its covalent conjugation with a lipid anchor for incorporation into immunoliposomes [205]. The CD data displayed no major alterations either of the secondary or tertiary structures suggesting the retained antigen binding activity of the derivatized antibody.

By measuring ICD bands generated upon binding of haptens (di- and trinitrophenyl derivatives), CD spectroscopy was shown to offer a new and powerful approach for studying and comparing the fine structure of the combining sites of antibodies of similar specificity and to probe the reformed site resulting from the reassociation of heavy and light chains [206].

Hydrophilic β-CyDs added to insulin solution caused CD spectral changes indicative for dissociation of the insulin aggregates to monomer or lower-order aggregates [207].

For developing a carrier for oral delivery, insulin was incorporated into chitosan/alginate nanoparticles. Far-UV CD spectra demonstrated the preservation of insulin structure during the nanoparticle formulations as well as after its release from the particles under gastrointestinal simulated conditions [208]. Despite of the presence of asymmetric centers of chitosan and alginate, the high optical transparency of these compounds allowed to measure the protein CD curve down to 190 nm.

Far-UV CD spectra indicated profound, irreversible structural changes of interleukin 2 caused by transient surface association with the infusion pump/catheter tubing system used for long-term delivery purposes [202]. The biological activity of the delivered protein was dramatically reduced by ≈90% after a 24 h infusion program.

pH and temperature dependency of CD spectra have been utilized for characterization of the recombinant anthrax antigen, showing highest thermal stability within the pH range of 6–8 [209]. CD spectroscopic screening of various stabilizers required to prevent the aggregation of the antigen helped to select compounds showing the most effective stabilization on secondary and tertiary structure of the anthrax protein.

Far-UV and near-UV CD spectra of diphtheria toxin and toxoids were taken to compare their secondary and tertiary structure. Near-UV CD spectra have shown that among the inactivation methods applied for preparing toxoids, acetylation and methylation of lysine residues hardly but glutaraldehyde and formaldehyde treatments drastically altered the protein tertiary structure [196,197]. In contrast, the far-UV CD spectra were essentially the same, indicating that secondary structure was unaffected by the detoxification process.

The anti-microbial preservative benzyl alcohol is widely used in the formulation of multi-dose parenteral products. Such agents, however, can greatly accelerate formation of non-native protein aggregates. In addition to the potential loss of biological activity due to aggregation, the presence of aggregates can cause adverse responses in patients. The addition of benzyl alcohol at 0.9% (w/v) to liquid formulations of human interferon-γ caused gradual decrease in the near-UV ellipticity values indicating the loosening of protein tertiary structure. This interaction pre-disposed the formation of high molecular weights protein aggregates as demonstrated by dynamic light scattering. Effects of the protein concentration, buffer components, buffer concentration on the aggregation were also studied by recording changes in the near-UV CD spectrum [201].

Analysis of ICD spectra of dye–HSA and dye–enzyme complexes served as an aid for the selection of dyes suitable to prepare sorbents for protein purification [210]. In addition, measuring the extinction of extrinsic CD signals of the complexes upon addition of various agents helped to establish the materials necessary for the elution of proteins bound on the sorbent.

#### *2.2.2.3 Comments*

- There are a range of various computer programs available for calculating the percentage of different structural motifs from the far-UV molar CD data of proteins, thus precise determination of the protein concentration is important [17]. In general, a basis set of reference proteins of known secondary structure is used to calibrate these methods by providing information on CD contributions of the various types of secondary structure existing in real proteins [37,211,212] (Fig. 6). These methods should be applied with caution for peptides, because globular proteins are used in the reference sets.
- It is a common practice to use the mean residue concentration (MRW) for displaying far-UV CD spectra of proteins and peptides as mean residue ellipticity units ($[\Theta]_{MRW}$). In contrast, near-UV and visible region of the CD spectra are reported in molar ellipticity ($[\Theta]$) or in $\Delta\varepsilon$ units in terms of protein or protein subunit molarity. It is important to differentiate between these kinds of data expression and to clarify the basis on which the molar concentration is calculated.
- Distilled water is the optimal choice for recording far-UV CD spectra of proteins and peptides. Buffers used for such purpose must have a low absorbance. Maximum absorbance of the samples should do not exceed 1.0 AU (including solvent and cell) [17,37].
- Particles of nanometer size (aggregates, impurities) in the sample solution may cause significant light scattering and thus overestimation of the protein concentration determined by UV spectroscopic method. Consequently, molar CD values will be lower which might be problematic for quantitative comparison of CD spectra of the same protein isolated from different biopharmaceutical formulations [213].
- Far-UV CD spectra of proteins might be insensitive for protein aggregation if it does not alter the secondary structure [201].

***FIGURE 6*** *Secondary structure analysis of an 81 amino acid yeast killer toxin from its far-UV CD data. (a) CD spectrum of the toxin in water and a spectrum calculated by reconvolution of the discrete structural contributions determined by the Convex Constraint Analysis method. (b) Results of deconvolution of the CD spectrum of the toxin into CD component curves of six pure secondary structural motifs. Adapted and modified from Ref. [212].*

### *2.2.3 Liposomes*

*2.2.3.1 Summary* Liposomes are the most clinically established nanometer-scale drug-carrier systems which provide a means to alter the biodisposition of hydrophobic drugs, genes, vaccines, as well as imaging agents. Among the biophysical techniques applied in the field of liposome research, CD spectroscopy can be used for

- detection of successful incorporation of drugs into liposomes [214–216];
- evaluation of the molecular state (e.g., monomer-aggregate, metal-complex) of drugs entrapped in the lipid environment [214,216,217];

- following the stability of liposomal preparations in the function of various environmental parameters (pH, temperature, time, etc.) [218,219];
- assessing structural integrity/conformational changes of therapeutic agents formulated in liposomes [220–222].

*2.2.3.2 Selected Examples* CD spectra of the chiral anthracycline antibiotics doxorubicin, daunorubicin, idarubicin and idarubicinol were compared in aqueous solution and in the presence of large unilamellar vesicles. Changes of CD profiles of the drugs indicated that both doxorubicin and daunorubicin bind to membranes in monomeric form. In contrast to this, the highly hydrophobic idarubicin and idarubicinol form small molecular associates within the bilayer involving 2–3 drug molecules, membrane cholesterol, and phosphatidic acid [216].

Taxol (paclitaxel) and its derivatives (docetaxel) are novel chemotherapeutic agents introduced to the clinical practice for treatment of malignant diseases. Due to their poor water-solubility, both paclitaxel and docetaxel require a complex solvent system for commercial formulations. Regarding their better toxicology profile, liposomal-encapsulated form of taxanes is a promising avenue for parenteral administration of these drugs [223]. CD spectroscopic evaluation of formulation characteristics can provide the information necessary to develop stable taxane-liposome preparations [214]. High similarity of the CD spectra of taxol measured in methanol and in liposome-incorporated state at low drug/lipid ratios indicated molecular solubilization of the drug in the lipid membrane. Upon increase the drug/lipid ratio, prominent changes of the taxol CD bands were observed which signify the drug destabilization and aggregation. By recording CD value of liposome-encapsulated taxol around 295 nm in the function of time enabled comparison of temporal stability of various formulations. In addition, quantitative analysis of CD spectral data permitted estimation of the fraction of taxane incorporated in the liposome membrane.

When protein or peptide pharmaceuticals are formulated in liposome delivery systems it is important to check their structural integrity on association with and after dissociation from membrane bilayers. Far-UV and near-UV CD spectra of human interferon-$\gamma$ recorded in liposome associated state and after desorption from liposomes showed no substantial difference compared to the native protein indicating full retention of both the secondary and tertiary structure [220].

CD spectroscopic investigation of the secondary structure of liposomal vasoactive intestinal peptide (VIP) revealed significant increase in the $\alpha$-helical content upon interaction of the peptide with phospholipids compared with the predominantly random coil form in aqueous solution [221]. The enhanced *in vitro* activity of the liposomal VIP was correlated with this structural transition since the $\alpha$-helix is the preferred conformation for VIP–receptor interactions.

CD spectroscopy is particularly useful for probing aggregation state of the strongly hydrophobic chiral polyene antibiotics like amphotericin B (AmB), filipin, and nystatin in liposome formulations [224]. The asymmetric centers of the macrolide ring render the molecular associates chiral (supramolecular chirality). Positive–negative CD peaks at 325–330 and 343–348 nm are assigned to the

chiral associates of AmB, while three positive peaks at higher wavelengths (378, 397, and 412 nm) are indicative to the monomeric state of the drug. Relative intensities, shape, time- and temperature [218,219] dependence of these CEs give valuable data on the monomeric–oligomeric drug equilibrium, localization of AmB molecules inside liposomes [217], interaction of AmB with plasma components [225] and help to determine the optimal conditions when the drug self-association is minimal [226].

#### *2.2.3.3 Comments*

- Intense light scattering of large liposomes distorts the CD spectrum making difficult to record CD signals of drugs incorporated. Accordingly, the light scattering interference must be reduced to a minimal level. This can be achieved by the reduction of the concentration of liposomes, using a short path length cuvette, and by a brief sonication of the sample solutions prior to the CD measurement to decrease the size of liposomes.

### *2.2.4 Gene Delivery Systems*

*2.2.4.1 Summary* Gene transfer represents an important treatment option for several genetic and acquired diseases with concrete perspectives of clinical application. Gene delivery systems are generally divided into two categories in terms of gene transfection carrier materials: viral and non-viral systems. For non-viral systems, cationic/anionic/neutral lipids and polymers complexed with chromosomal/linear/plasmid DNA or with synthetic oligonucleotides are frequently used due to their advantageous biological and formulation properties [57]. These systems are capable of condensing DNAs and improving their *in vivo* stability and cellular uptake.

Due to presence of chiral sugar units both single- and double-strand nucleic acids acquire helical secondary structure in which chiral exciton-coupling arises between the $\pi$–$\pi^*$ transitions of the stacked nucleobases resulting strong CD signals below 320 nm [10,30,57]. For nucleic acids, peak position, shape, sign, and intensity of the CD signals are functions of the nature of base-stacking interactions and the helicity of DNA. Thus, CD spectra present excellent indicators of various structural forms (A, B, C, D, T, Z) of nucleic acids. CD spectral modifications of nucleic acids induced by their interactions with gene delivery components can be applied to

- demonstrate complex formation between nucleic acids and the carrier [57];
- evaluate and compare the conformation and organization of nucleic acids in different formulations [227–231];
- study the organizational state of nucleic acids within the gene delivery vehicles under variety of experimental conditions (pH, temperature, ionic strength, etc.).

*2.2.4.2 Selected Examples* Amine-substituted gemini surfactant-based nanoparticles containing plasmid DNA were examined by using various methods including CD spectroscopy [227]. The red shift and intensity changes of the CD bands suggested distortion of the B-DNA conformation as a result of compaction of the DNA molecule by the surfactant.

Conformation and condensation of DNA complexed with cationic polymers were studied by CD spectroscopy. Depending on the charge ratio applied, B → C conformational transition of the double helix [228] and the appearance of polymer-and-salt-induced $\Psi^{-}$-type DNA [229], a highly condensed chiral tertiary DNA structure were observed.

CD studies indicated the right-handed B-DNA → left-handed Z-DNA conformational transition during anionic lipoplex formation [232]. Comparison of chiroptical profiles of the anionic and cationic lipoplexes suggested significant differences between the conformational transitions of DNA in the two formulations. It was noted that the formation of Z-DNA may contribute to the high transfection efficiency of anionic lipoplexes.

#### *2.2.4.3 Comments*

- Most gene delivery vehicles are heterogeneous, non-covalent complexes of DNA, and the delivery agent. Therefore, consistency of the procedures used to prepare the complexes is essential for the reproducibility of CD spectroscopic data.
- In general, chiral compounds (e.g., cholesterol and its derivatives) used to synthetize carrier components of gene-delivery formulations have negligible CD contribution above 220 nm and thus allow CD signals of DNA to be clearly resolved with little or no interference from the lipid component. In contrast, using some chiral cationic polymers such as polylysine, polyarginine, polyhistidine which display strong intrinsic CD signals below 230 nm may limit the spectral region suitable for CD scanning.
- Due to inadequate purification, chromosomal DNA can be associated with histones and other nuclear proteins, which will potentially contribute to the CD spectra.
- Since diameter of the gene-delivery particles are typically greater than 120 nm and display a heterogeneous size distribution, effects of light scattering to CD as well as UV absorption spectra (flattening effects) have to be taken into consideration [57,230].

## 2.3 CD Spectroscopic Investigation of Drug–Biopolymer Interactions

### *2.3.1 Drug–Protein Binding*

*2.3.1.1 Summary* There is a close analogy between chiroptical phenomena described for drug–CyD and drug–protein interactions. Similarly to CyDs, proteins are also asymmetric hosts, thus protein-bound ligands might display ICD bands, too. It is to be noted that most CyDs show no intrinsic CD activity above 220 nm but due to the presence of several asymmetrically perturbed chromophores proteins display intrinsic CD activity in the near-UV region (240–320 nm) which can disturb measuring ICD bands of ligands in this region. In addition, aromatic amino acids, especially tryptophan side chains might participate in generating ICD bands of protein-bound ligands via non-degenerate chiral exciton coupling mechanism [21,105,233,234]. Further mechanisms

which can also be involved in CD spectroscopic manifestation of ligand–protein interactions are

(a) the chiral perturbation of electronic transitions of the guest molecule by the asymmetric protein matrix [21,79,235];

(b) the helical (twisted) conformation of the chromophoric moiety of the ligand molecule adopted at the binding site [21,235–238];

(c) intramolecular chiral exciton coupling between the chromophoric parts of a protein-bound ligand molecule [21,42,235];

(d) intermolecular exciton coupling between two (or more) guest molecules bound close to each other (<10 Å) to the protein matrix [21,42,235].

Practical applications of ICD spectra in studying drug–protein interactions are as follows:

- Measuring ICD bands is a valuable diagnostic tool for demonstration of drug–protein binding interactions (Table 4).
- Quantitative analysis of ICD spectroscopic data measured at different [drug]/[protein] molar ratios (CD titration) allows determination of the number of binding sites per a protein molecule and the affinity constant [105,235,237,239–242].
- By monitoring ICD signals of marker ligands known to bind to specific binding areas of the protein upon addition of a drug, binding site of the latter can be identified (CD displacement method) [42,240,243]. Alternatively, displacement/competition studies can be carried out by measuring the change of the ICD signal of a protein-bound drug with unknown binding site upon the addition of site markers [242].
- Drug-binding properties of native, recombinant, chemically modified forms [233,235,244] or genetic variants [42,237,240] of the same protein can be assessed by comparative evaluation of ICD spectra.
- The species differences of drug binding parameters of pharmaceutically important proteins can be evaluated by ICD methodology [245,246].
- Comparison of extrinsic CD spectra of drug-native protein and drug-mutant protein complexes may help for identification of amino acid residues involved in the drug-binding mechanism [233,247].
- Allosteric, cooperative, and competitive interactions between different ligands bound to the protein host can be investigated by measuring ICD spectra [42,248–250].
- Conformational changes of the protein provoked by drug binding can be studied by measuring far-UV CD spectra [102,251].

*2.3.1.2 Selected Examples* Numerous papers are available reporting CD spectroscopic studies of binding of various therapeutic drugs to the principal transporter proteins of human blood, HSA, and $\alpha_1$-acid glycoprotein (AAG). The binding was detected and binding parameters were determined by measuring and analyzing ICD spectra of the protein-bound drugs (Table 4).

**TABLE 4 Selected Examples for Drug–Human Plasma Protein Binding Interactions Studied by ICD Spectra**

| Drug | HSA | AAG |
|---|---|---|
| Antimalarial agents | | [240] |
| Benzodiazepines | [252] | [252,253] |
| Coumarin anti-coagulants | [248] | [253,254] |
| Dipyridamole | | [255] |
| Imatinib | | [237] |
| NSAIDs | [256–258] | [253] |
| Phenothiazine neuroleptics | | [259] |
| Prazosin | | [260] |
| Sulfonamides | [261] | |
| Thyroxine | [262] | |

The site II specific marker (±)-ibuprofen decreased the ICD signal of leukotriene $B_4$ bound to HSA indicating the binding of leukotriene to the sub-domain IIIA [243].

Changes of the ICD spectrum of HSA-bound diclofenac and carprofen proved the site-II-to-site-I displacement of the drugs upon addition of ibuprofen [263].

Comparison of ICD spectra of the tyrosine kinase inhibitor imatinib obtained with the main genetic variants of AAG helped to assign the high-affinity binding site of the drug on the F1/S variant [237].

Interaction of several substrates (e.g., dihydrofolate), coenzymes (NADPH), and inhibitors with dihydrofolate reductase was demonstrated by measuring extrinsic CD bands [105,264] and the binding parameters were estimated from ICD data of the enzyme-bound ligands [105]. ICD spectra showed the formation of reductase–NADPH–methotrexate ternary complex [105].

The strong negative CD band of colchicine at 340 nm vanished or was greatly reduced upon its specific binding to tubulin. Decrease of the CD values enabled to estimate the colchicin–tubulin association constant [241].

The potent immunosuppressive drug rapamycin (Sirolimus) mediates its effects via binding to an intracellular protein termed FKBP (immunophilin). CD spectroscopic investigation of rapamycin/FKBP complexes disclosed very subtle conformational changes of the ligand undetectable either by NMR or by X-ray crystallographic methods [265].

ICD spectra of acetylsalicylic acid indicated its binding interaction with human myeloma immunoglobulin [266].

The binding of rifampin to human tear lipocalin was monitored by measuring alteration of intrinsic CD spectrum of the chiral drug above 300 nm [242]. Using the change in CD activity at 359 nm, the binding parameters were calculated. The binding site of rifampin was identified by CD displacement experiment performed with palmitic acid known to bind in the central cavity of the protein. pH dependence of the CD spectrum of the rifampin–tear lipocalin complex showed that the drug may be released from the protein in acidic environment. The results suggested the possibility of using tear lipocalin as a specific carrier for the delivery of rifampin to tuberculous lesions that are acidic and rich in fatty acids.

Specific changes in the far-UV CD spectrum of the rat β-adrenoceptor protein obtained in the presence of (−)-epinephrine, but not with its (+)-antipod, indicated the stereoselective binding of the pharmacologically active (−)-enantiomer [102] (Fig. 7).

Far-UV CD spectra demonstrated that upon binding of the anti-depressant benzodiazepine agent alprazolam the α-helicity of hemoglobin subunits are gradually lost [251].

#### *2.3.1.3 Comments*

- Strong intrinsic CD activity of proteins masks ICD signals below 240 nm. Accordingly, protein binding of drugs showing no light absorption above this region cannot be studied by ICD method.
- The main disadvantages to using far-UV CD spectroscopy to detect protein structural changes upon ligand binding are that *1)* a fairly substantial conformational change is required to detect increase or decrease of CD band intensities below 240 nm, *2)* the CD spectrum provides no information on which sequences of the protein are involved in the conformational rearrangement.
- Depending on the intensity of the CD signals, relatively high protein concentration is required to perform CD titration or CD displacement experiments ($\approx 10^{-5}$–$10^{-6}$ M in 1 or in 2 mL sample volume).
- Drug-protein association constants much higher than $10^7$ $M^{-1}$ cannot be determined by regression analysis of ICD titration data since the binding equilibrium is completely shifted toward the protein-bound species.
- Similarly to drug–CyD complexes, drug–protein binding interactions might also be "CD silent" resulting in no ICD signal despite of the formation of the complex [258,267,268].
- If a drug possesses two (or more), a high affinity and a low affinity CD inducer protein binding sites, it should be considered that due to the different local asymmetry, these sites might induce overlapping but different CD band patterns. In such cases, sign inversion, band shift or appearance of additional CEs can be observed during the titration procedure [269,270].
- For ICD measurements aimed to study ligand–ligand competition or allosteric interactions, the one participant must be optically transparent (e.g., valproate, fatty acids) [242] or its intrinsic/extrinsic CD band(s) must be separated from CE of the other ligand [258,271].
- Intrinsic CD profile of sterically restricted chiral molecules (e.g., steroids) might be little affected upon protein binding.

### *2.3.2 Drug–Nucleic Acid Interactions*

*2.3.2.1 Summary* Nucleic acids are obvious targets for drug intervention since modification of their structures clearly will have significant biological implications. The principal non-covalent binding modes of drugs to double-stranded nucleic acids

***FIGURE 7*** *CD spectra of (a) rat lung membrane protein (50 μg/mL) in phosphate buffer, (b) enantiomers of epinephrine (200 μM) in phosphate buffer, (c) rat lung membrane protein (50 μg/mL) in combination with (+)-epinephrine (200 μM). The spectral summation of data obtained in (a) and (b) is also provided for comparison. (d) Rat lung membrane protein (50 μg/mL) in combination with (−)-epinephrine (200 μM), along with spectral summation. Adapted and modified from Ref. [102].*

include groove binding (e.g., distamycin A, netropsin, Hoechst 33258) or intercalation (e.g., daunorubicin, doxorubicin) between the base pairs [272,273]. In single-stranded polynucleotides drugs can bind only by intercalation. Other agents, such as cisplatin, mitomycin C, and ecteinascidins, form covalent linkages with DNA, while duocarmycin, bleomycin/pepleomycin, and enediyne antibiotics cause DNA backbone cleavages [273]. Nucleic acid association of drugs may give rise to various kinds of ICD spectra depending on the mode of the binding and the value of the [drug]/[base pair] molar ratio. Intercalation (typically planar, aromatic molecules) and groove binding at low [drug]/[base pair] values result in a single, positive, or negative CE [274–277]. Upon increasing the [drug]/[base pair] ratio, the ICD pattern may become bisignate [275,278] displaying both positive and negative CEs within the principal absorption band of the drug. As more and more drug molecules bind and stack together in chiral orientation relative to each other in the minor or major groove of the duplex, the exciton interaction between their electronic transitions will be more and more dominant resulting characteristic biphasic ICD peaks. It is to be noted that compared to the intercalative mode, ICD signal of ligands bound in the minor groove is stronger by one order of magnitude [279,280].

Applications of drug–nucleic acid binding induced CD spectroscopic changes are as follows:

- Measuring ICD activity verifies the occurence of drug–nucleic acid binding interaction.
- Intercalative and non-intercalative binding modes can be distinguished by comparison of ICD spectra obtained under different experimental conditions (e.g., low/high [drug]/[base pair] ratios, various temperatures, ionic strength) [274,278].
- Nucleic acid binding mode of a ligand can also be studied by competition experiments: monitoring the effects of addition of a known minor/major groove binder or intercalator compound on ICD band of the ligand–nucleic acid sample helps to distinguish between the binding modes [274].
- From ICD data obtained by titrating a drug into a solution containing fixed concentration of a polynucleotide (or vice versa), the binding constant and the number of base pairs covered by a single drug molecule can be determined [110,278,281].
- Comparison of CD spectra of drugs obtained with synthetic polynucleotides with alternating (e.g., poly[d(A-T)]·poly[d(A-T)]) and homologous sequences (e.g., poly(dA) ·poly(dT)) informs on the sequence preference of the drug binding [282,283].
- Changes of the intrinsic CD pattern of polynucleotides elicited upon drug association might also be utilized for characterization of the binding interaction [283,284].

*2.3.2.2 Selected Examples* Comparison of changes in the intrinsic CD spectra of ofloxacin enantiomers measured in the presence of natural and synthetic

polynucleotides revealed enantioselective binding of the enantiomers in the minor groove of B-DNA [285,286].

Binding of the anti-cancer agent 9-hydroxyellipticine to calf thymus DNA and synthetic polynucleotides was studied by various biophysical techniques including CD spectroscopy [278]. The CD data showed that the drug adopts two main binding modes, intercalative and groove binding, which involves the formation of drug oligomers in the major groove. ICD values proportional to the concentration of the DNA-bound drug enabled to calculate the equilibrium binding constant.

CD spectroscopy was employed to study the dimerization of the topoisomerase I poison chiral topotecan and the increase of the dimerization process upon topotecan–DNA binding [287].

Alteration of the intrinsic CD spectra of a DNA dodecamer indicated the binding of the enediyne antibiotic calicheamicins which provokes marked conformational change of the B-form DNA. Binding constants were estimated based on analysis of CD spectral changes [284].

Addition of calf-thymus DNA to the solution of the optically inactive anti-neoplastic mitoxantrone gave rise to ICD bands above 450 nm [288]. Behavior of the CEs recorded at various [drug]/[base pair] ratios suggested intercalative binding mode. No ICD activity was seen with the Pd (II) complex of mitoxantrone indicating that the presence of the metal ion prevents intercalation of the drug between the base pairs.

Due to the presence of 11 stereocenters and several chromophores, the anti-cancer agent paclitaxel displays intrinsic CEs below 300 nm. Intensity changes and shift of these CEs observed in the presence of DNA suggested that paclitaxel molecules go from an aggregated state to a non-aggregated form upon binding with the double helix [289]. Comparison of CD spectra of mixtures of alternating and homologous synthetic polynucleotides with paclitaxel indicated AT sequence specific binding of the drug [282].

Nucleic acid association of ligands showing no light absorption above 220 nm can also be followed by measuring binding generated changes in the intrinsic CD profile of DNA. Though the lowest-energy UV transition of the natural lipid, oleic acid is below 220 nm, its binding to double but not to triple stranded oligo- and polydeoxyribonucleotides was clearly demonstrated by recording dramatic changes of DNA CD bands [283]. It was deduced from the spectroscopic results that oleic acid recognizes AT base pair motifs by minor groove binding.

#### *2.3.2.3 Comments*

- The ICD approach is unsuitable to identify specific nucleotide units or base pairs with which a given drug interacts since ICD data provide averaged structural information only.
- Modification of intrinsic CD spectra of chiral drugs can also be used for verifying drug–polynucleotide binding interactions [285,286]. However, it can occur that the strong intrinsic CD profile of sterically restricted chiral drugs remain unaltered despite of nucleic acid binding [290].

- For drugs showing light absorption in the 220–310 nm region, the measured CD spectrum will be the sum of intrinsic (nucleic acid) and extrinsic (bound drug) CD contributions. In such cases, it might be difficult to resolve the dominant nature of spectral changes since drug binding may alter the secondary structure of polynucleotides and this modified CD pattern can be mixed with the extrinsic CD signal of the drug [280,291–293]. This phenomenon is less important for proteins showing low-intensity near-UV CD activity compared to the much stronger CD bands of polynucleotides.

## 3 APPENDIX

Taking into consideration the time consuming compilation process of the Encyclopedia, update of the manuscript finalized in 2008 seemed to be necessary. The Appendix overviews the most relevant literature references published between 2008 and 2010 together with some previously overlooked works which are related to the applications of CD spectroscopy in the field of pharmaceutical sciences.

### 3.1 Stereochemical Characterization of Organic and Inorganic Compounds

Theoretical bases of CD spectroscopy and its applications in stereochemical studies of bioactive natural products with special emphasis on the CD exciton chirality method have been summarized [294].

### 3.2 Structural Characterization of Biopolymers

The most important applications of ECD and related CD techniques in biomolecular (proteins, peptides, nucleic acids) and nanostructural analysis (nanoparticles, nanocarriers) have been summarized [295]. Extended by a brief theoretical description, Schweitzer-Stenner *et al.* have provided an overview on how absorption and CD spectroscopy can be used to identify and characterize different conformational states of cytochrome *c* in solution [296].

### 3.3 Investigation of Biopolymer–Biopolymer Interactions

Applications of CD spectroscopy in structural studies of glycosaminoglycans and glycosaminoglycan-protein binding interactions have recently been reviewed [297].

***3.3.1 Enantiomeric Purity Determination Using HPLC-CD System*** Applying simultaneous UV and CD detections and *g* factor calculation, a simple, rapid and enantioselective method for the separation and determination of carnitine enantiomers has been developed for their quantitative analysis in dietary supplements and pharmaceutical formulations [298]. The method lacks of derivatization step and of a chiral support to separate the enantiomers and enables to calculate an e.e. of the potentially harmful D-carnitine.

The separation of benzoxathiepin diastereoisomers and their chemical impurities on an achiral sorbent has been followed by CD/UV detection. The determination of chemical purity was achieved with UV detection whereas the diastereoisomeric purity was determined by plotting the *g* factors versus the e.e. of each couple of enantiomers [299]. A mathematic model was developed to express the diastereoisomeric excess vs. the e.e. of each pair of enantiomers. Practical advantages and limitations of analytical assays based on HPLC-CD and CD/UV methods for screening of enantioselective enzyme-catalyzed reactions have been discussed [300].

## 3.4 Drug–Cyclodextrin Complexes

Alterations of far-UV CD spectrum of the organoantimonial drug, meglumine antimonate have been measured to investigate its association with β-CyD and the effects of heating and freeze-drying on the complex [301]. Modification of the intrinsic CD band of simvastatin upon its interaction with α-, β- and 2-HP-β-CyD has been used to study the inclusion geometry of the complexes [302].

## 3.5 Protein and Peptide Pharmaceuticals

The book entitled "Modern Techniques for Circular Dichroism and Synchrotron Radiation Circular Dichroism Spectroscopy" provides a comprehensive and up-to-date account of CD spectroscopy and its application to structural biology. A separate chapter discusses in detail the experimental aspects of CD spectroscopic characterization of biopharmaceuticals [303].

The conformational stability of the therapeutic fusion protein abatacept has been probed at various pH and temperature values by monitoring far-UV CD spectra [304].

Phenol used as a preservative in pharmaceutical insulin preparations binds to specific sites on the insulin hexamer and act as an allosteric effector. The binding isotherm constructed using CD data which were obtained by titration of the insulin hexamer with phenol allowed to calculate the dissociation constant [305].

In the course of developing a process for obtaining stable dry protein formulation of interferon α2a and immunoglobulin G, CD spectroscopy has been used to compare the secondary and tertiary structure of the reconstituted proteins with the structure of the native form [306, 307]. Intranasal formulations of the therapeutic peptide salmon calcitonin have been assessed by various methods. Far- and near-UV CD data supported structural similarity in secondary and tertiary structures of the peptides formulated in chlorobutanol and in benzalkonium chloride as preservatives [308].

'Solid-state' CD spectroscopy method has been proposed to study the surface-adsorbed conformation of therapeutic proteins following microencapsulation [309].

As has been determined by CD spectroscopy, secondary structures of chemically synthesized immunogenic anti-malarial peptide vaccines show certain characteristic structural configurations which can aid the easier design of additional immunogenic and protection-inducing peptides [310].

### 3.6 Gene Delivery Systems

A novel book chapter has been published focusing on the practical applications of CD, UV absorption, IR, and fluorescence spectroscopies for the structural analysis of the oligonucleotide component of nonviral gene delivery vectors [311].

### 3.7 Drug–Protein Binding

AAG binding interactions of several kinase inhibitors evaluated by using ICD spectra of the complexes have showed high-affinity protein association of most compounds [312]. Changes of the ICD bands of dicoumarol bound to the 'A' variant of AAG provoked by the anxiolytic agent deramciclane have proved that AAG can simultaneously accommodate both drug molecules [313]. Analysis of the ICD data showed that the presence of deramciclane enhanced by five-times of the AAG binding affinity of dicoumarol. AAG variant selective binding of nine basic drugs in clinical use has been examined by measuring their effects on extrinsic CEs of the 'F1/S' and 'A' variant selective CD label dicoumarol and acridine orange, respectively [314]. An interesting application of CD spectroscopy is its use to study mechanisms by which anesthesia occurs, i.e. the examination of the effects inhaled anesthetics (e.g., halothane, isoflurane) on protein CD spectra and to study the thermodynamic stability of proteins in the absence and presence of anesthetics to estimate the binding energetics [315–318].

### 3.8 Drug–Nucleic Acid Interactions

Theoretical and practical aspects of how circular and linear dichroism spectroscopy can be used to provide information about drug-DNA systems have been outlined [319]. Photogenotoxic potential of several pharmaceutical substances (e.g., chlorpromazine, furosemide, quinine) has been studied employing CD spectroscopy to analyse their DNA binding properties [320].

## 4 ACKNOWLEDGEMENT

This work was supported by research grant of OTKA K69213.

# *Good Manufacturing Practices—Steps to Improve Quality*

**John E. Snyder**

## 1 GOOD MANUFACTURING PRACTICES: GOOD BUSINESS PRACTICES

With the advent of Current Good Manufacturing Practices (CGMP) in 1978 (1) came a major shift in the way the Food and Drug Administration (FDA) enforces drug quality in the pharmaceutical industry. Simply stated, the quality of a product is no longer determined by the results of end-product tests alone. It must also be documented that product has been manufactured, packaged, and held according to the written procedures that comply with CGMP regulations.

In fact, the Food, Drug, and Cosmetic Act goes so far as to say that a drug product shall be deemed to be adulterated if the methods used in, or the facilities or controls used for, its manufacture, processing, or holding do not conform to or are not operated or administered in conformity with current good manufacturing practices (2). Therefore, regardless whether a drug product is materially defective, deviations from CGMP regulations cause drug products to be adulterated within the meaning of the Act, and violative articles are subject to seizure and condemnation in district courts.

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing,*
Edited by Shayne C. Gad

Likewise, the United States Pharmacopoeia (USP), the compendium of U.S. official analytical methods, agrees that although every unit of product must conform to requirements, this cannot be established by product testing alone. Rather "data derived from manufacturing process validation studies and from in-process controls may provide greater assurance that a batch meets a particular monograph requirement than analytical data derived from an examination of finished units drawn from that batch (3)."

The assurance of product quality down to the individual unit level is important because that is what patients take—individual tablets, capsules, injections—often daily and often lifelong. With this in mind the premise of CGMP is to drive quality by enforcing regulations that require manufacturers to document their capability to operate in a state of continuous control. However, fear of enforcement action is not the best inspiration for sustaining a quality operation. CGMP regulations must be viewed as an enabler of good business practices that achieve the shared goals between the FDA and the manufacturer of product safety, efficacy, potency, purity and other quality attributes. Thus the recognition of CGMP as a catalyst for quality, rather than a business antagonist, is the first step to improve quality.

When examined from a business perspective, CGMP regulations cover aspects of daily manufacturing operations that are the very foundation upon which businesses compete, which is to have reliable product supply that meets customer requirement with economic control of quality (4). We can make this connection between complying with CGMP and enabling good business practice by broadly considering the business implications of six major themes in the regulation.

## 1.1 There must be Product and Process Knowledge to Achieve Consistency (5)

This means that we will understand the science and technology of the product development from beginning to end, which led to the routine operation of converting raw materials and packaging components into the final packaged dosage form.

A range of knowledge is necessary such as supplier capabilities to meet requirements; equipment and instruments selection and operating ranges; and test methods and specifications used to evaluate acceptability. We know the process control points that are critical and those that are not. We know which upstream factors cause downstream affects and just how far to the edge of the range we could go without affecting important outcomes. The reason we are knowledgeable of our process is because the variables have been studied during the product development phase before being transferred and accepted into the routine manufacturing environment.

We also have conducted studies and documented that when we operate according to our approved manufacturing and packaging instructions, we have a high degree of statistical confidence that our product will meet requirements and fall in a normal random distribution comfortably within the limits of our specifications. Since these specifications are based upon outcomes in clinical studies, we have proven and validated our capability to manufacturer product that delivers intended results.

For the business, product and process knowledge translates into a reliable and efficient operation. A very low probability of rework or reprocessing, and minimal process-related down time is expected that enables a predictable, right-first-time manufacturing schedule and a reliable supply of products to customers. Also every batch of product has a pedigree linking it to the manufacturing and testing methodology used for clinical studies, which was the basis for the approval of the drug product application. When errors or unintended drift occurs within the operating parameters and specifications, a data-driven conclusion on the product effect can be readily determined by referring to the collective body of process knowledge.

## 1.2 Manufacturing Process Resides within a Controlled Facility and Environment (6)

The facility is designed to preclude mix-ups and contamination by controlling the paths of materials, components, in-process and final drug product, and people. We design-in the ability to clean manufacturing, packaging, and holding areas by selecting appropriate materials for construction of floors, walls, and ceilings, and that the cleaning agents and methods achieve the degree of cleanliness or sanitization required. We ensure that the supply of critical utilities such as air, water, gases meet standards for intended use. Environmental temperature and humidity meet the requirements to maintain the stability of raw material, in-process, and final product. We carefully consider material storage space and layout to support the in-process product flow and warehousing of raw materials and components to prevent mix-ups.

Protecting operators is critical in terms of what they touch and breathe, as well as how operator movement, behavior, and traffic flow through the facility could potentially contaminate product. So proper HVAC systems, air flow patterns, and defined spaces are engineered and monitored. We provide for the safety and ergonomic needs of our operators. We consider the security of the facility and to control access of employees and visitors and prohibit the access by rodents and other pests.

For the business, this means efficient and predictable movement of materials from dock to stock. Product rejection and re-inspection due to contamination by pharmaceutical dust, operator handling, or foreign product are engineered out of the process. Public relations issues from costly recalls and customer complaints are prevented due to mix-ups in product and labeling due to inadvertent commingling of materials. When a facility works with the process and people, there is a positive work environment and reduced human resource issues.

## 1.3 Sources of Unwanted Variation must be Prevented from Impacting the Process (7)

The facility is kept in good repair and good housekeeping is practiced. Equipment and instruments are well maintained by placing them on preventive maintenance and calibration schedules based on manufacturer recommendations and extent of use so that we have confidence in the accuracy and precision of in-process readings from equipment and test instruments. We ensure that everyone is trained for their specific

job duties and has a working understanding of their role in complying with CGMP. When new employees are hired, they demonstrate to responsible management their ability to perform tasks as trained and established in written procedures in order to control the human variable.

We understand that we must operate in a state of control that enables us to predict a successful product outcome. Therefore, we guard against anything that has a potential effect on the state of control of our operation. Proposed changes to anything we do are carefully, if not skeptically, considered on a technical level to ensure that the impact is understood and acceptable—even if the proposed change is viewed as an improvement. The effectiveness of changes is confirmed against the pre-established intended result.

For the business, this means that a check and balance exists for when innovative process technology and business practices are introduced to an established product manufacturing process. Innovation should always be explored, especially if it translates into increased productivity and the ability to better compete in the marketplace. The intent of CGMP is never to deter technological advances, rather to combine process knowledge with regulatory intent to achieve "mindful compliance (8)." However, caution is exercised by demanding data-driven conclusions regarding product impact and equivalence as filed in the regulatory application in order that product integrity is maintained.

## 1.4 There must be a Record of the Manufacture and Controls used to Make a Product Batch (9)

This includes written instruction such as procedures, protocols, test methods, master batch records that describe the manner in which work activities must be performed. We understand that these instructions form much of the content of specific job training and that these instructions must be written clearly at the level of the person performing the operation. Informal instructions are not permitted and only those that are written, current and approved are available in the work area.

Documentation also includes the recorded output from written instructions. We recognize that activities are recorded at the time they were performed and results obtained at the time they were observed. The person actually doing the work, and likewise the actual witness for critical steps sign and date the record. We establish documentation conventions to preclude perception of fraud or misunderstanding as to the intention of the entry such as significant figures, correcting entry errors, and handling unused fields in records. Taken collectively, batch-specific documentation establishes an audit trail of the complete history of any given batch of product. The importance of documentation is underscored by the fact that FDA inspections routinely involve a documentation review as evidence of following CGMP, more than product testing.

For the business, documentation is legal evidence of product manufacture. It is the record of meeting regulatory compliance and product quality requirements and the basis upon which product is released into the market. It is an essential source of information for data mining for technical studies, process improvement as well as

for an investigation into a process deviation or a customer complaint. Documentation that supports a validated and stable process in general, as well as specific batches of product is invaluable for product liability defense cases.

## 1.5 Problems must be Detected and Handled Appropriately when they Occur (10)

This requires that we establish feedback mechanisms that report negative trends and failures of products, processes, and systems. Such feedback is obtained from established processes that handle customer complaints, returned goods, annual product reviews (APRs), performance metrics, deviation and failure reports from the manufacturing floor, and quality control laboratories.

Feedback detection systems are described in procedures and include the type of issues, metrics, and trends that are routinely reported and reviewed, as well as those that are quickly escalated to management responsible for governance.

We respond to reports from detection systems by determining the impact on product, whether or not the product has been distributed (11). This involves a thorough investigation into the facts of the situation, determining the root cause or most probable cause, the degree of risk, the necessity of interim controls while the issue is corrected and prevented from recurring (12). Depending upon the degree of risk, the product may need to be voluntarily recalled from commerce. Responsible management is always informed of regulatory inspections, recalls, significant issues being investigated, and key performance metrics.

For the business, these requirements provide the processes to continuously measure the effectiveness of the quality system, the state of control of the operation, as well as highlight anomalies for immediate action and improvement. This means that a quality improvement program is embedded within the regulation, which is focused on error cause removal, and that many of the classic tools of quality are directly applicable. When compiled into periodic reports, management with executive responsibility is provided with an important input for corporate governance and an essential input into the planning process of the business.

## 1.6 The Quality Unit is Responsible for Testing, and Implementing and Measuring the Effectiveness of the Quality System (13)

An independent quality unit is traditionally separated into two functional units: quality control and quality assurance. Quality control is a laboratory or measuring function such as analytical chemistry, microbiology, immunochemistry, biological, attributes inspection, or physical testing that examines raw materials, components, in-process material, and final packaged product against pre-determined specifications. We ensure that quality control has adequate laboratory facilities to perform their function. We typically operate a quality control unit as a work center with planning values and resources for testing cycle times that are balanced to meet the volume demand and production schedule. Laboratory operations may be performed by

a contract company that has been approved by a qualification protocol and operate under a quality agreement.

Quality assurance has several responsibilities that are required by CGMP. They are responsible for establishing the systems that make possible all the other themes described above, as well as measuring the effectiveness through audits and quality metrics. They have the responsibility of reviewing and approving CGMP documents as well as proposed changes before they are implemented. Quality assurance is responsible for reviewing and approving the adequacy of investigations related to manufacturing deviations, failures to meet specification, and customer complaints. They review production batch records and other manufacturing records and are empowered to make the decision to release product into the marketplace. We are careful that responsibilities are assigned to quality assurance are not a conflict of interest, for example, not creating situations where quality assurance performs work for which they are expected by regulation to review and approve.

For the business, the quality unit is the objective function within the operation that assists management to exercise its governance responsibility. The quality unit is uniquely positioned to provide responsible management with performance measures that not only report on nonconformance, but also enable management to anticipate and identify potential product quality and regulatory compliance risks. The management challenge is to allow the quality assurance function to operate independently, yet integrate the function into the business. This often is achieved by balancing independence for assessing and reporting with accountably for establishing systems that are both compliant and efficient and their promoting ownership for product quality and compliance outcomes across all functional areas.

This broad survey of themes illustrates how interrelated the concerns are between CGMP regulations and business. It is interesting to note, however, that CGMP regulations do not prescribe in all cases exactly how a business is to comply. Although there may be FDA guidance on how to interpret and apply regulations, FDA is thankfully silent on how exactly to design a system, step-by-step for any specific business application.

It is tempting sometimes for someone to transplant procedures from their previous company experience—just changing the letterhead. It may come with an endorsement that says, "The FDA had no problem with this at my previous company." Here is where it must be emphasized that one size truly does not fit all, and that there is no such thing as a universal template for what a company should specify in its procedures.

In fact, a lot of harm can be done to a business in the name of experience when there is a failure to recognize that a quality system is more than a set of written procedures. A procedure is just words on a page unless it takes into consideration the environment it is in. For example, it is quite possible, say, for a document management procedure to require that a simple, clarifying wording change in a test method to go through the same document review and change control systems as major change in equipment with little regard for the rigor of review being commensurate with the risk being managed. Although, compliance is achieved if the procedure is followed, such an approach could negatively impact a business that needs to be nimble in order to respond quickly, yet effectively to market changes to be competitive.

A pharmaceutical business needs to be both CGMP compliant and competitive. Since there are many ways to implement the CGMP regulations, the best one is the one that works to serve both ends. This fact opens a door of opportunity to enhance both compliance effectiveness and business efficiency by improving the design and implementation of the CGMP quality system.

The first step to improving quality is to recognize that the CGMP regulation is an enabler of good business practices as well as product and process quality. The quality system implemented for CGMP compliance is a worthy target for improvement, since enhancement will be realized for both quality and the business.

However, if a quality system is more than a set of procedures—more than words on a page, then what is a system? Understanding the answer to this question is the second step to improving quality.

## 2 GOOD MANUFACTURING PRACTICES: GOOD SYSTEM PRACTICES

The concept of a system can be illustrated by a radio. The antenna is not a radio; neither are the diodes, resistors, or speaker. However, each of these parts has a purpose and each part works together so that collectively they are the radio and operate predictably regardless of who turns it on. Over time the radio has evolved in its reliability to transmit and replicate sound with greater fidelity so that now we can enjoy music as if we were in the very midst of the orchestra. Over time improvement has been directed toward each part. As one part was improved, others followed. Each worked with the others to enhance the overall quality of the radio. Improved quality was an output of improved radio parts that work together as a system.

So it is with the CGMP quality system. Quality is an output of all the individual parts of the system working together. The degree to which each part of the quality system is designed to meet requirements—and, interacts, or relates well with each other and with the business environment is the degree to which a quality output is achieved.

Thus, the second step to improving quality is to understand that a system is comprised of many parts that must interact well together. Like the illustration of the radio, the component parts of the CGMP quality system must work well together to be effective.

When evaluating how well the parts of a CGMP quality system work together, it may be useful to consider the three levels of features that promote effective interaction: those that are *within*, *between*, and *around* the parts of the system.

Let us examine the first level of features that enhance interaction that are *within* a given part of the system.

### 2.1 Written Procedures

This might seem obvious, since throughout the CGMP regulations we read that instructions for meeting the requirements are to be in writing—and followed. The term

"established" is typically used in the regulatory and pharmaceutical fields to mean that instructions on how requirements are met are in writing, approved by the quality unit, and implemented into the workplace by training all affected personnel. Without procedures it is difficult, if not impossible to control the human variable, or defend how a company intentionally expects work to be performed. Procedures are at the core of the training curriculum and a company defense; therefore, considerable attention must be given to the adequacy of written procedures and competency-based training programs to ensure procedures are translated into performance in the work area.

It is common for a company to have an architecture of policies and procedures that go from the general requirements at the corporate level to the more specific site standard operating procedures. Architecture provides a balanced outline and structure to the library of interlinking procedures at a site, or network of sites throughout the corporation. Guidance is commonly provided to standardize the format, style, and level of writing so that the entire body of written instructions fits together. Even with guidance, not all are gifted with the ability to write clearly and preserve the balance of the body of procedures as a whole. Unfortunately, it is far too common for a procedure to be written to plug a gap, rather than to consider where the instructions would more appropriately fit in the process. For this reason, authoring procedures should be vested with the best of writers, and the review and approval process should ensure the highest of writing standards are preserved. In short, if one were to view the table of contents for the body of policies and procedures, it should resemble the logic and orderliness of the table of contents of a college textbook.

## 2.2 Process Flow

The process flow follows and facilitates the order in which work is actually performed. Flowcharting is the tool most often used by owners and stakeholder teams to visualize the process when either creating a new process or improving an existing process. A process flow diagram can promote conversations and enhance understanding between functions that have a stake in how a current process operates, or how a new process will operate before the procedure becomes effective. Independent persons can also add value to the mapping process by watching for redundancies, re-cycling of activities, or other inefficiencies that may be deeply held conventions by those close to the process. Process flow diagrams also enhance procedure training by showing trainees the big picture, key interactions, and decision points, as well as their role in the overall effectiveness of the process.

Incomplete, inefficient, and disjointed processes open the door to informal practices to develop over time. "Failure to follow the procedure" is a familiar regulatory inspection citation. However, it does not always reflect an unwillingness or inability of the user. It may reflect the lack of a fluid, practical or understandable way of doing the job. The term "work around system" is often used to describe an unauthorized, sometimes easier, way to get the job done. Although a "work around system" cannot be condoned in the pharmaceutical industry, no one says that the right way has to be confusing. It is important for a process to be complete, but not difficult to follow.

## 2.3 Established Responsibilities

Clearly defined responsibilities, including designees—or back-ups are important to ensure that the appropriate individuals are qualified and authorized to take on the specified roles. There are some instances where councils convene regularly for a specific purpose, such as an environmental review board or material review board. In these cases, the responsibility of the individuals who participate, as well as the group as a whole should be described in the procedure. If a responsibility includes review and approval, the procedure should specify what the reviewer and approver are signifying by his or her signature to be clear and emphasize the importance of this responsibility.

Aside from the various responsibilities for the process, it is important for there to be an owner who has overall responsibility for the performance of a given part of the system. The owner is responsible for ensuring that the process keeps up with evolving compliance requirements and current industry practice. The owner is also responsible for being the spokesperson for the process, knowing how well the process is working, and continually seeking way to improve it. Without clear ownership and defined responsibilities, there can be organizational confusion and inefficiency.

## 2.4 Qualified Decision-Making Authority

All processes have decision points. While some decisions may be very straightforward, others may require critical thinking skills to weigh the available information, assess the risks and implications in order to render the best decision. Therefore, care must be taken where decision-making is vested to ensure that the appropriate qualified persons make decisions. Consideration should be given whether an individual, or a group makes a decision. Decisions by groups tend to be slower in order to reach consensus, but there is more buy-in. Decisions by individuals are quicker, but more difficult to implement. There are some situations that may require the escalation of a decision. Escalation may be invoked when an individual or team cannot reach a decision or when the risk involved warrants participation in the decision-making process by more senior management.

As discussed earlier, the unique role of the quality unit in decision-making must be preserved as defined in the regulation. However, the quality unit is well served by consulting other operating functions to make informed decisions.

## 2.5 Records Document Work Performed

A process will always include pathways for records to be completed to document process inputs and outputs, as well as signatures and dates of those who perform and verify steps. Records include forms, batch records, logbooks, recording charts, printouts, and other means of permanent documentation of process information and results. It takes skill to design simple and user-friendly records that require all the essential, value-added information to be captured. Instructions on how to complete the record must be given in sufficient detail in a related procedure to achieve consistent

documentation across multiple users. Procedures and records should be reviewed together when changes are made to avoid inconsistencies.

An emphasis must be placed on careful documentation. It is common that general training is given on good documentation practices to promote clear and consistent entries, as well as documentation practices to prevent perception of fraudulent records.

Specific training on each record is also essential for users to understand how to properly document specific work, and to understand the reason behind each entry. Only through complete, accurate, and timely records can investigations be conducted and the manufacturing history be told. In fact, so essential are records that without them there is no product. For this reason, original records are controlled through an established document management process to keep them secure during use and catalogued in a storage area, or archive that prevents loss or damage.

## 2.6 Measurement of Performance

Each part of the CGMP quality system should establish the metrics that are to be reported and reviewed. The procedure should provide the frequency, distribution and review and approval responsibility. The metrics selected should indicate how well the system is operating, and what the system is detecting. These two dimensions are necessary to give a complete picture of the effectiveness of the quality system. For example, a Pareto analysis of customer complaints will show what the system is detecting. However, a report on the number of new complaint files opened, the number complaint files closed during the period and the cycle time of pending complaint files (0–30 days; 31–60 days; 61–90 days, etc.) will tell how well the system is operating.

Operating metrics are often viewed as "efficiency" or "business" metrics, not CGMP. However, nothing could be farther from reality. As discussed above, CGMP and the business are really inseparable. In the earlier example of complaint handling, operational metrics may be the only indication that a backlog liability is mounting, which is a CGMP issue. Backlogs of any kind within the quality system such as complaint handling and manufacturing deviation investigations, preventive maintenance, training, annual product reviews, validation and requalification are signals of inattention to activities that can identify and prevent future failure. Backlogs of any kind are most always associated with a reactionary work environment (14).

In some cases, a diagnostic metric may be necessary to go a level deeper to pinpoint where specific remedial action is required. In the complaint handling example, if a significant backlog were revealed by the operating metric, a life cycle metric would breakdown the number of days a complaint file dwells at the various stages of the handling process. This diagnostic metric could reveal, for instance, if the bottleneck was due to repeated review cycles between manufacturing and quality to rework a better-written investigation. This fact would lead to targeted improvement initiatives. The use and interaction with performance measures is part of the responsibility of the system owner to manage the process; and it is the responsibility of the owner to escalate issues when the performance metrics show unfavorable trends that are beyond his or her control to quickly resolve.

System failures that result in a serious business loss and regulatory enforcement action are often traced to the inability to self-detect and self-correct failures or trends toward failure in sufficient time for management to intervene at the most economical time to resolve the problem. When there is a product, process or system failure, or a field alert, recall or regulatory action, there should always be an examination into the performance metric that was missing or unheeded that could have alerted the right persons at the best possible time to take appropriate action. Performance metrics enable an organization to move from a reactionary to an anticipating environment. More about performance metrics follows later.

As an example of the above first level of interactions *within* a part of the CGMP system, let us consider features of a supplier qualification program to assure control over suppliers.

One would expect that a qualification process begins with the selection of the candidate supplier for the specific material to be procured. The process would further include how the material and the manufacturer would be evaluated and approved for use.

Responsibilities would be defined for all who participate in the process such as product development who identifies the grade and specifications for the material; purchasing identifies a reliable supplier that is capable of meeting the specifications at the right price; and quality assurance conducts the audit of the supplier against the appropriate standard and assesses inherent risk in the ability of the supplier to meet the specifications. The responsibility for preparing the supply agreement will be with Purchasing, as well as the quality agreement by the Quality unit.

The decision to use a supplier may be made jointly between purchasing and quality assurance, or perhaps a material management team. The quality unit gives the final approval by placing the supplier on the approved supplier list and determines the audit frequency and audit technique to be used based on risk to the process, product, and patient. If there is a change in supplier, the quality unit approves the technical justification through the change control process.

One or more files or databases are defined in the procedure as the formal records that document the supplier qualification process. This would include the supplier audit and responses; copies or references to supplier performance at in-coming inspection; deviations that point to a material as the root cause; as well as corrective and preventive action (CAPA) plans.

A quarterly supplier performance report will be issued to the functional heads of product development, manufacturing, purchasing, and quality assurance. The report includes the approval status of suppliers, noting particularly those that are associated with laboratory or manufacturing failures along with the status of corrective and preventive action (CAPA). Additionally, the status of supplier audits, planned versus conducted, is provided.

All these features reflect interactions *within* the supplier qualification component of the CGMP quality system. Each of these features is important for the system to operate effectively and efficiently.

In our continuing list of system features, let us now examine the second level interactions, which are *between* parts of the CGMP quality system.

## 2.7 Defined Relationship between Parts of the System

The CGMP quality system is a web of interdependent relationships. The effectiveness of one part is dependent on the effectiveness of other parts. Each part of the system has inputs and outputs that link one to the other, and deficiencies in one place can have far-reaching effects elsewhere in the system.

Take CAPA for instance. A CAPA system is only as effective as the ability to detect failure or trend toward failure throughout the operation. One cannot correct or prevent what one does not detect. Thus, all inputs must be identified where a deviation in product, process, or system could occur, and processes must be in place to link these as inputs to the CAPA process in order to effectively investigate, correct, and prevent recurrence. Likewise, the output of the CAPA process is a link back to the originating area of the deviation to verify that the measures taken to prevent recurrence were indeed effective, as well as to keep the area informed where the deviation originated. Therefore, CAPA must be linked to other parts of the CGMP quality system, which must be carefully identified as inputs and outputs. Without these defined relationships, the process can become an island of activity creating a false sense security—a lot of motion and resources, but no real benefits.

It is a common practice for a procedure to have a list references. The most effective use of a list of references is to help identify the interrelated systems. This is particularly useful when a change is made to the procedure. The reference list tells you where else to look that may be impacted by the change. Much like an ecosystem, one cannot make a change in one place without examining the effect on the others.

It is also worthwhile to map the interrelationship. Much like the process flow mapping in the first feature, process mapping between parts of the CGMP quality shows the practical ways the parts interrelate. This also promotes a better understanding between all persons involved in executing the work.

## 2.8 Ownership of Dependent Processes

Much like having an owner for each component part of the CGMP quality system, an owner of interrelated processes operates at a higher level where the dependent processes come together. There is no better way to break down the silos within an organization than to create a network of owners that are responsible for the performance of the dependent processes that invariably operate cross functionally.

Continuing with the supplier example, an owner of dependent processes would include all the processes that insure materials used for CGMP purposes from the point of identification of supplier to its use on the manufacturing floor. The overall owner, business process owner if you will, is identified by name as well as the individual process owners. When such a team is identified and challenged with the responsibility and authority to make data-driven decisions and measurable improvement to materials management, a powerful interdisciplinary resource is created to manage major segments of the business. Rather than creating *ad hoc* teams to react to the problem-of-the-day, ongoing process teams as described here should be communicating regularly and interacting with performance metrics to prevent failure and continuously

improving the operation. This approach creates a natural structure to manage and improve the business, as opposed to popular "quality improvement teams" that are sometimes directed to "spotty" problems and not well integrated with the operation on a continuing basis. Continuous improvement requires continuous integration.

As an example of this second level of interaction *within* a part of the CGMP system, let us consider the dependent processes of transferring technology from a sponsoring operation to a contract manufacturing operation.

The business process owner at the contract manufacturer may be the Technology Transfer function, which typically understands the technical capability of the operation and the functional and regulatory requirements to communicate well with the business development function, internal operating areas, and customer.

A procedure is in place and in use to direct the transfer and timing to ensure all requirements are met. The content of a quality agreement is also procedurally established to identify those who are responsible, accountable, consulted, and informed between each entity for the myriad of activities involving shared responsibilities. The procedure guards against practices that affect variability and reliability. For example, effort is made not to introduce differing ways of working at the contractor site, and to safeguard essential steps from the transfer process affect reliability.

Team members include process owners from facility and process engineering, validation, purchasing, operations, training, and quality who understand what it takes to establish a reliable manufacturing process. This would include requirements for the facility, utilities, equipment, and operational capabilities; the implication of the customer bill of materials (BOM) for identifying approved suppliers; validation to ensure that quality attributes, critical control parameters are defined and translated into manufacturing processes and procedures; operators are trained in the associated procedures and batch records. Team membership may also extent to the sponsor company.

The component part process owners, as led by the overall business process owner, continually examine the effectiveness of the interrelated process to ensure that the requirements are met in the most effective and efficient way by reviewing the performance measures that each brings to the table; making data-driven decisions and setting measurable goals to enhance business performance.

Finally, let us conclude our list of features as we examine the third level interactions, which are *around* parts of the CGMP quality system.

## 2.9 Supporting Organization

Having the right organization structure and number of people with the right skills is not only essential for executing the work, but is essential to operate in compliance and in a state of control. However, this is often a management challenge in a competitive marketplace where headcount and cost of goods sold (COGS) is always scrutinized to improve profitability. However, there are opportunities to streamline organizations that support the CGMP quality system and reduce costs without wandering into compliance problems.

There is an erroneous view that all things quality and CGMP belong in the quality unit. This notion duplicates functionality, enables lack of ownership for quality and compliance in the operation areas, and drives up costs. For example, nowhere is it required that the quality unit should perform training, validation, and investigations. Many organizations place these functions within the quality unit, for the sole reason that this function is thought to be more knowledgeable about the regulatory requirements to perform these activities. While the quality unit has responsibility to ensure a system is established for these functions, and it has a review an approval authority, the activities do not necessarily belong within the quality unit. In fact, this could be viewed as a conflict of interest. The education, skills, and experience should more appropriately reside in the disciplines of human resources, engineering, and manufacturing supervision respectively. If the skills do not exist in these functional areas, then the strategy should be to build the capabilities within these parts of the organization, which is more cost effective than adding headcount to the quality unit to double-team the work. The more a quality unit moves toward its basic regulatory commission, the smaller the quality organization needs to be, while the knowledge in the operating areas is increased.

However, those who control operating budgets must understand that a CGMP quality system must be in place to comply fully with the regulations whether one batch or a thousand batches are produced. For example, regardless of production volume documents are still managed; equipment and instruments are still calibrated and maintained; changes are still made and must be technically justified; the environment is still monitored; annual product reviews are still written, analyzed, and reviewed; complaints and manufacturing deviations are still investigated; metrics are still performed, reviewed and actions taken—the list goes on. Therefore, there must be a sufficient staff level to establish, maintain, and operate the system as the price of admission into the industry.

Nonetheless, there are aspects of most systems that do relate directly to volume such as the number of laboratory tests for in-coming materials, in process controls, and final product; the number of batched records reviewed; the number of deviations investigated; and so forth. Thus, the CGMP quality system should not be above review for cost reduction opportunities, but making a distinction between those aspects that are variable based on volume from those that are fixed is important to prevent the quality system from collapsing.

## 2.10 Supporting Infrastructure

This is the assortment of bricks and mortar, computer systems, and software programs—even workspace that either helps, or gets in the way of effectively implementing the CGMP quality system to support the operation.

For example, inadequate warehouse space can prohibit segregation and adequate cleaning; manual record keeping can inhibit the ability for "look backs" to go through voluminous historical records to identify similar product complaint and trends; and insufficient number of computer terminals can make computer-aided training modules difficult to deploy, schedule, and complete on time; or outdated hardware and

software versions of engineering and maintenance systems can make these difficult to service.

Although infrastructure is often less tangible, it nonetheless can affect productivity and the ability to adequately comply with CGMP regulations.

Automating a quality system may not always be the answer to improving the infrastructure, particularly for small operations and low volumes, since computer system validation regrettably introduces another level of complexity to maintain from a regulatory perspective. Bricks and mortar issues can sometimes be resolved creatively, and employees often hold the answers. However, when examining the infrastructure issues, it is important to have as the super-ordinate goal to facilitate information and process flows and to eliminate non-valued-added steps, redundant files, and time delays.

These features of interrelationships *within*, *between*, and *around* a CGMP quality system help us to take a broader view of the nature of a system. If one were to have the misfortune to be the recipient of an FDA483 or a Warning Letter, one might pause before taking the typical approach in the name of system thinking of simply making a revision to a standard operating procedure and attaching it to the response. Indeed, a CGMP quality system is indeed more than words on a page.

Thus, the second step to improving quality is to recognize that a system involves the myriad of interrelationships that work together to provide predictable and sustainable results. An examination into the effectiveness of the relationships within, between, and around the CGMP quality system is another worthy target to identify opportunities for improving quality.

But real-world experience says that things do not go perfectly all the time. In fact, CGMP regulations acknowledge this by a provision for handling deviations through a process of technical review, technical justification, and documentation. However, the question is not whether a pharmaceutical manufacturing operation should expect only normal, random variation to be operating all the time. Rather, the question is whether the operation has the capability to detect deviation from the norm and respond appropriately with good decisions to bring the operation back into control. This brings us to the third step to improve quality: performance metrics.

## 3 GOOD MANUFACTURING PRACTICES: GOOD METRICS PRACTICES

There is no CGMP regulation that specifies the metrics to be reviewed to evaluate the performance of the quality system. Drug regulation 21CFR211.180e requires a rather belated review of records at least annually to determine whether or not changes are needed for specifications, manufacturing process, or controls. In essence, this is a retrospective analysis of process capability to determine whether changes may be required to ensure a manufacturing process is stable and operating well within specifications and operating control limits.

Closer to the intent is found on the medical device side where 21CFR820.20 provides for a management review of the suitability and effectiveness of the quality

system at defined intervals. Also, the review of "quality data" is mentioned as a source of information for identifying existing and potential causes for quality problems in 21CFR820.100 as part of the CAPA system. Thus, it is presumed that quality data is being collected that would reflect the adequacy of the quality system.

The International Conference on Harmonization (ICH) Pharmaceutical Quality System Q10 guidance document offers some detail to "manage and continually improve the pharmaceutical quality system." The first is a formal periodic review of key performance indicators such as complaints, deviations, CAPA, and change management processes, as well as self-assessments, regulatory inspections, and customer audits. The second is a review of factors that impact the quality system such as new regulations, guidance, and industry trends, as well as changes in the business that could result from innovation and new strategies. Finally, the guidance suggests that the outcome of the review should promote quality system improvement, evaluation of resources, and enhanced communication or escalation of issues to senior management.

Appropriately, the regulations and guidance have left it to individual companies to determine their own approach to applying specific performance metrics to manage the quality system, and the range of industry practices widely varies.

On the rather simplistic side, some companies search for a single index to know how well the quality system is working so that a 9.5 provides more assurance than a 4.0 that the quality system is working well and the operation is in a state of control. Some have argued that the stock price of the company is the single most important numerical indicator—though rather lagging in its ability to point to an emerging quality problem. However, after a problem manifests itself in a supply interruption, or after a regulatory enforcement action becomes public information, then this single indicator will certainly come into play, though in an unfavorable direction.

There are some who believe that the true measure of the adequacy of the quality system is the outcome of regulatory inspections where fewer observations are better than many, and the absence of a negative is an implied positive. Some go as far as to compare the number of observations for the current year to a running average over the history of the company to serve as a barometer of their system as though some statistical treatment can be applied to these events. Such believers are eventually caught off guard and typically surprised when an inspection does not go well—or when regulators rebuke them for having to be inspected into compliance.

On the other end of the spectrum, there are companies that have an exhaustive set of metrics that roll up into a dashboard that summarizes massive amounts of information about the entire operation at a glance. Embedded somewhere are elements of the quality system such as corporate and internal audits. Line items are often rolled up to an overarching category and reduced to a color code that flashes the attention of the reader to the problem areas. Backup data is typically displayed in a spreadsheet, which may be compressed onto as few pages as possible. However, rarely are trends toward failure detected in this manner, or connections made between the dots for sporadic, but significant emerging issues.

Still other approaches major in graphic displays as though the objective is to use every quality tool in the pocket guide. Though appealing to those who prefer pictures

to columns of numbers, the point can be missed amongst the hackneyed pie charts and graphs—particularly in the absence of well-written analysis to direct the eye of the reader.

These scenarios are not uncommon and reflect differing views and attempts to satisfy a range of management interest and attention spans. The challenge is not only to prepare meaningful performance metrics, but also to make the business case for the value of management being engaged with quality system metrics with the same interest as sales figures from the various territories and regions it serves. In both cases, relevant data are reviewed against expectations, and when expectations are not met, adjustments are made and the effects monitored. When expectations are met, there are rewards and celebrations. Whether its sales or CGMP quality system performance metrics, it is unreasonable to expect that all numbers come in on target all the time. However, it is a reasonable expectation that management engages with performance metrics in order to manage the performance of the company (15). For both sales and the CGMP quality system, the effects on the business are significant in order to sustain the operation and to compete long-term in the marketplace.

Thus, the third step to improving quality is to manage the effectiveness and the efficiency of the quality system through meaningful performance metrics and action-oriented management reviews.

There are many kinds of tools and techniques for reporting, trending, and summarizing data. There are many textbooks and pocket guides to choose from that deal with metrics. In the end, the right metrics are the ones that work; and those that work answer three basic questions: Is the system being managed or functioning as expected? What is the system detecting? What is causing the problem?

The first question is of fundamental importance, since a poorly managed or poorly functioning system may give a false impression—such as no news is good news. Operational metrics are designed to give us information about the system itself.

Let us take the self-quality audit system as an example. An operational metric could be the number of audits performed versus planned. Another could be the number of overdue audit report responses versus number of audit reports issued. So for instance, if the gap between the number of audits planned and performed begins to increase over time, then an inquiry should be made into the reason for the backlog. Reasons could point to performance, absenteeism, competing priorities, or even unwillingness for the auditee to allow audits to be scheduled. Likewise, a backlog in overdue audit responses may signal such things as the lack of attention to the task or an inability to prepare a response to the satisfaction to the auditor. Another example is the analytical laboratory. An operational metric could be the cycle time from the time a sample is collected to the time the result is officially reported versus the planned time. An increase in the cycle time could be a function of increased testing volume, a problem with the method or instrumentation, or perhaps lack of a proper test schedule.

The second question is only of complete value after the first question is answered. The issues or the magnitude of the issues detected by the system presume that the system is operating as intended to be able to detect problems. For example, given the

complaint handling system is operating well, what complaints are we seeing? Given the laboratory operations systems are working well, what do the results tell us? Given the deviation system is operating well, what non-conformances are we experiencing? And so forth.

So it presumes, for instance, that the Pareto analysis used as a detection metric to report the top compliance issues detected by the system were based on all the planned audits, not just the two out of the twelve that were actually performed; or that the favorable cycle time for reporting lab results was based on all tests required for release, not just finished product.

Operational metrics and detection metrics each tell part of the story. Reporting only one or the other is a common flaw in the application of metrics, and both are necessary for proper interpretation and decision-making.

The third question is answered by diagnostic metrics, which attempt to direct focused action toward the underlying reason for problems detected by properly functioning systems. Continuing with the self-quality audit example, with the operational metrics indicating that all planned audits were performed and response reports closed, the issues identified in rank order by frequency detected that the most frequent audit finding was failure to follow the company policy on good documentation practices. Upon reviewing this fact at the regularly scheduled management review, it was decided to look into this matter further to diagnose the problem in order to direct a targeted initiative toward specific improvement. The quality group was asked to further break down the findings to determine the type of records and the work center where the documentation errors were found.

This exercise resulted in the discovery that most of the documentation errors occurred in product batch records related to the sterile manufacturing operation. Armed with this information, the manufacturing process owner along with owners of related systems such as technical services and quality assurance examined these specific records and interviewed employees in the specific area. It was discovered that since this particular work group and process technology was recently added to the capability of the site, and that the timetable for the technology transfer process was compressed, the training requirements were truncated, which included training on good documentation practices. It was also discovered that the master batch records transferred with the process were error prone, since data fields in many instances were inconsistent with documentation requirements.

By using diagnostic metrics, management was able to direct specific action. In this example, the sterile manufacturing work group was given the requisite training. Additionally, management directed a review of required standards and training for technology and personnel transferred to the site—while they also reflected upon the effect of their previous decision to cut the training time.

Although practices may vary across companies for how quality system performance metrics are selected, reported, and reviewed, developing a common approach within an organization enhances communication and the overall effectiveness as an essential business tool. Here are seven attributes of good metrics practices that will help performance metrics for the quality system to be clear, concise, concrete, comparative, and cogent.

### 3.1 Metrics and their Calculations are Defined

This is particularly important for common metrics that are reported across functions within a site, or metrics that are reported between sites. The source of the data and how the metric is calculated is important to ensure they are derived the same way. Definition and standardization ensures that there is no misunderstanding about what exactly is being reported, so that true comparisons can be made and pooling of data can be done. Let us take customer complaints as an example. It is important to know whether both prescription and OTC products are included, and whether the complaints include both medical and product attribute complaints. Also the denominator such as per number of batches distributed per time period must be established.

### 3.2 Metrics are Comparative and Time-Related

For metrics to answer, "Are we getting better, worse, or the same?" metrics need to be presented in a way that enables us to compare performance over a relevant time period and set of conditions. For example, the variability of a critical dimension of a packaging component from a supplier before and after implementation of corrective measures requires the need to know dates of the turn key or phase-in implementation, as well as supplier lot number information to be able to measure the improvement at incoming inspection. Another example is the need to know the production shift, manufacturing line, and employees where the improved production batch record was directed in order to show if there was a reduction in errors within the same group compared to the previous version.

### 3.3 Metrics have Direction and Scale

Decide on the direction on the graph that will be the universal direction that indicates improvement. It can be very confusing when up means better one time, and down is better the next within or between reports. The most common practice is for "down" to signify "better." This practice is most likely associated with the "Zero Defects" quality school, where zero defects are the quality standard. Also, be sure that the scales on the axis are chosen appropriately for sensitivity of the measurement. Changing the scale on the graph between reporting periods and using overly large units of scale are the oldest tricks in the book to obscure a negative trend.

### 3.4 Measure the Opportunity, Not the Success

This guidance is perhaps the most controversial between optimists and pessimists. The optimist might rather focus on the number of investigation completed, rather than the number still open. The pessimist might rather see the number of batches with errors, rather that those that are correct. It is true that "Right First Time (RFT)" sounds a lot better than "Wrong First Time (WFT)." However, measuring the opportunity is not intended to convey pessimism, rather to focus on the exposure and risk.

## 3.5 Metrics are Actionable

Metrics should answer the questions previously discussed: Is the system being managed or functioning as expected? What is the system detecting? What is causing the problem? Anyone presenting metrics for management review should be prepared to interpret the data and make recommendations. When action is warranted, then it should be clear who is accountable for achieving favorable results, and all the participants that affect the outcome should be identified to partner in the initiative. Goals and target dates should be set, as well as the frequency to receive updates on the metrics to ensure that the initiative is supported and getting results.

## 3.6 Metrics Enable an Organization to Predict Performance and be Proactive

Perhaps the most important benefit of quality system metrics is the capability it gives to the organization to predict a problem and proactively address it at the most economical time, before it becomes a more costly quality problem or a regulatory enforcement issue. Therefore, systems should define a trend, and to specify when special action is required when a trend is identified. Some systems may follow the simple rule of "One is a point, two is a line, and three is a trend." When traditional statistical process control (SPC) techniques are used, then the Westinghouse Rules may apply whereby a trend or an outlier is flagged based on some practical rules of thumb-based statistical theory. The customer complaint handling is an example of a system that needs to err on the side of a false positive trend to detect an early product liability issue. For certain, trends need to be applied to the systems that manage the most significant regulatory and financial risks in order to ensure escalation of issues to higher levels of management as quickly as possible.

## 3.7 Align Metrics with the Business Plan

Quality system metrics are very well suited to provide a component to the business process of setting company goals and personal performance objectives. They add the "specific and measurable" dimension. Nothing could be more powerful as a serious driver for change than to align quality system metrics with the business plan. In fact, recommendations for targeted improvement should be the natural outcome of the ongoing management review of quality system metrics. One of the most significant contributions by the quality function is to bring data-driven targets to the business planning sessions, as well as to objectively report on the results from the previous year targets.

The question often arises as to who should be responsible in an organization for establishing metrics practices and reporting quality system performance for management review. Although there could be a number of suitable answers to this question, a case can be made for this to be the responsibility of the quality unit.

The quality unit is the only functional organization with a job description in the Code of Federal Regulations. Among other duties prescribed, it has the responsibility

to independently ensure an effective quality system is established, and that the effectiveness of the quality system is evaluated. Metrics are probably the single most effective means to make that evaluation, far more effective that audits. Audits provide feedback for a point in time on whatever the focus of the audit may be at the time. However, metrics provide an ongoing intelligence across the entire quality system—and the business. Because of the power of metrics, the quality function has a significant vested interest that metrics are solidly in place procedurally and in use behaviorally.

The fact that the quality function is responsible for the quality system is underlined by the fact that more warning letters are beginning with, "The Quality Unit has failed to ensure an adequate system is in place to"—then fill in the blank. The focus is turning to whether there is a strong and independent quality organization that is able to establish an effective quality system, and whether the quality system is capable of detecting a failure and righting itself in a timely manner through corrective and preventive action. Metrics is the quintessential tool of the quality function, which gives it a diagnostic capability.

For organizations that have a well-implemented set of quality system metrics, the way quality audits can be performed is revolutionary. In an effective metrics environment, routine internal quality audits are able to evolve and add value in ways that are unheard of within the pharmaceutical industry today. Audits could examine the validity and integrity of databases from which metrics are derived; confirm that calculations and metrics as reported for high risk areas are accurate; re-evaluate the appropriateness of metrics described in procedures; and examine whether quality systems should be enhanced based on regulatory and benchmarking surveillance. This is in contrast to the prevalent mode of simply conducting audits of departments against their existing procedure—regardless of how adequate they may be. An evolving audit function should be part of the vision for an enlightened, futuristic quality organization that is thoroughly embedded in a quality system metrics environment.

Reporting on quality system metrics should be the responsibility of the quality function. First, the weight of the regulatory responsibility for the quality system falls squarely on the quality function. Secondly, the independence and objectivity of the quality function puts them in the unique position to deliver the difficult messages often revealed by metrics. Company executives should nurture and welcome quality function "straight talk," which may be difficult for less independent functions to deliver.

Metrics also provide the quality function with a means to significantly contribute to the business planning process. Too often the quality function is not quite up to par where business planning is concerned. Unfortunately, business planning is often thought by quality professional to be the domain of the business units, or associates with business degrees. Nothing could be farther from the truth. Keep in mind that embedded in the wealth of quality system metrics is data about waste, errors, non-conformance, complaints, and all manner of other sources for cost improvement. Armed with quality system metrics, the quality function should be well prepared to offer each planning period to the executive team the three to five most significant issues that, when addressed, will result in annualized savings to the business, as well

as improve quality and reduce regulatory compliance risk. The quality function should also be able to provide data-driven evidence of improvement and savings for the initiatives identified the previous year.

Metrics reveal three possible states of a given element of the quality system: stable, event failure, and system failure.

The term stable is used to signify that the metrics are usual and expected; and comparable to a relevant period. For SPC applications, this description signifies "in statistical control" where only "common cause" or normal, random variation is operating. There is no statistically significant difference in means and variability between data sets; and that the data points are randomly distributed about the mean.

For example, metrics indicate that the number of investigations closed equals the number opened; and that the average time to closure is 20 days with few investigation exceeding 30 days; those that exceed 30 days are justifiable and approved; and that the average number of investigations per batch is stable at a low targeted level. These metrics have been maintained over the last 6 months. The conclusion is that the quality system for investigations is stable.

The term event failure is used to signify that the quality system detected an event or a non-conformance, either in the operation of the system or in what the system detected. For SPC applications, this description signifies an instance or instances of being "out of statistical control" due to an assignable cause. When the problem is corrected, the metrics indicate a return to the stable state.

For example, metrics indicate that there had been a delay in meeting the procedural deadline for APR reports for the second consecutive month. Further investigation into this operational metric showed that the delays corresponded to a vacancy in the position responsible for these reports. Although the issue might have been better tended to when the first overdue report was noted, the metrics did bring the issue front and center. The failure related to the vacancy event, and the system was brought back into control through a temporary assignment, as an interim control then was fully resolved when the position was permanently filled.

The term system failure is used to signify a breakdown in the operation of the system, or breakdown of whatever the system is detecting. For SPC applications this description signifies "out of statistical control" due to causes that generally affect the system from operating as established. To remedy a system failure requires an assessment against the 10 attributes of a system as described above.

For example, the FDA visited to follow-up on numerous field complaints on a critical care medical device due to the melting of a plastic connector used in a critical care device. The failure caused a malfunction of the device during patient use. An investigation revealed that a change from a brass to a plastic connector had been implemented as a cost improvement initiative. The change was expedited in order to capture the savings in the current quarter. Since the supplier of the plastic component was ISO certified and the connector was a standard catalogue item, the decision was made by the quality unit to approve the change. When the FDA asked to see customer complaint records, it was discovered that there were four additional complaints unnoted for this malfunction waiting processing due to a backlog.

There were multiple system failures in this example. The change control system failed to technically evaluate the effect of the change; the supplier qualification system failed to accept the plastic connector based on fit for purpose; the complaint handling system failed to detect associated complaints in a timely manner to be able to address the problem; the quality unit failed to ensure there was an adequate system in place, and further it enabled an improper decision.

Thus, an ongoing review of performance metrics is an essential means for corporate and site governance in order to know the state of the CGMP quality system, and to direct a data-driven response toward improvement.

## 4 CONCLUSION: GOOD MANAGEMENT PRACTICES

An exasperated company executive once declared that he was tired of their firm being a "learning organization." Puzzled by his comment, he further explained that he meant he was tired of all the "lessons learned" meetings that followed when there were quality problems, supply interruptions, and surprise findings from FDA inspections. He wanted the organization to become an "anticipating organization" that was capable of seeing further down the road and around the corner to be able to make adjustments before it was too late.

His comment led to an examination of the information that was collected and reported throughout the organization on their quality system and their state of CGMP compliance.

Reports centered on quality projects from their continuous improvement office. Regulatory compliance activity was limited to timeliness of closing out audit responses, and an indication that FDA had not visited during the reporting period. The report was dotted with reassurance of efforts to benchmark and their recent internal award for best-demonstrated practices across the company network.

It was clear from an analysis of the information and reports he routinely received that he had been flying blind. He had not been receiving the type of intelligence from the CGMP quality system that he needed to truly manage the regulatory compliance aspect of his business. In the final analysis, there was nothing much to base his confidence on the effectiveness of the quality system, or state of control of the operation. Yet, the operation was busy doing "quality."

Over time his paradigm shifted about the CGMP quality system. No longer was it the onerous obligation to satisfy hard-nosed FDA inspectors, rather a strategic imperative that supported his concern for patients and customers, and the ability to compete. The quality system was not just a set of procedures, but the strategic intent to align the organization and operate in a state of control—yet flexible in how the intent of regulations can be carried out. Most of all, "management review" was no longer empty, mail-drop report, rather an objective and data-driven cross-functional session that gave him confidence that the CGMP quality system was operating well, and directed attention to identified problems, unacceptable trends, and risks. This gave him the edge he was looking for to stay ahead of the problems.

In the end, he recognized that the CGMP quality system itself is a worthy target of continuous improvement to ensure that good business practices, good system practices, and good metric practices were applied—or one could sum up by saying good management practices—in order to compete and be worthy of patient trust.

## 1 INTRODUCTION

Drug manufacturing control requires high level and intensive analytical and chemical support of all stages to ensure the drug's quality and safety [1]. The pharmacopeia constitutes a collection of recommended procedures for analysis and specifications for the determination of pharmaceutical substances, excipients, and dosage forms that is intended to serve as source material for reference or adaptation by anyone wishing to fulfill pharmaceutical requirements. The most important analytical technique used during the various steps of drug development and manufacturing is the separation technique: high performance liquid chromatography (HPLC).

The key to a proper HPLC system operation is knowledge of the principles of the chromatographic process, as well as understanding the reasons behind the choice of the components of the chromatographic systems such as column, mobile phase, and detectors. A scheme of an HPLC system is shown in Fig. 1. A high pressure pump is

required to force the mobile phase through the column at typical flow rates of 0.5–2 mL/min. The sample to be separated is introduced into the mobile phase by injection device, manual or automatic, prior to the column. The detector usually contains low volume cell through which the mobile phase passes carrying the sample components eluting from the column. There are books describing the practicality of HPLC operation [2–11]. It is expected of any proper HPLC system that is used in the pharmaceutical laboratories to produce highly accurate and precise results, due to health-related issues of improper measurements. Every HPLC system must be qualified to comply with the strict demands from health authorities for high quantitative performance.

Quality standards in pharmaceutics require that all instruments should be adequately designed, maintained, calibrated, and tested. The approach that has been adopted in the environment of the analytical instrument has become known as the "Four Qs": design qualification (DQ), installation qualification (IQ), operational qualification (OQ), and performance qualification (PQ). Design qualification is performed at the vendor's site, and it is representative of the way an instrument is developed and produced, usually governed by International Organization for Standardization (ISO) criteria.

The IQ process can be divided into two steps: *pre-installation* and *physical installation*. During pre-installation, all information relevant to the proper installation, operation, and maintenance of the instrument is checked. Workers confirm the site requirements and the receipt of all of the parts, pieces, and manuals necessary to

perform the installation of the specific HPLC unit. During physical installation, serial numbers are recorded and all fluidic, electrical, and communication connections are made for system components. Documentation describing how the instrument was installed, who performed the installation, and other various details are archived.

The operational qualification process ensures that the separate modules of a system (pump, injector, and detector) are operating according to the defined specifications such as accuracy, linearity, and precision. Specific tests are performed to verify parameters such as detector wavelength accuracy, flow rate, or injector precision.

The PQ step verifies system performance as a whole. Performance qualification testing is conducted under real operating conditions in the analytical laboratory that is going to be using the instrument. In practice, sometimes operational and performance qualification blend together, particularly for linearity and precision (repeatability) tests, which can be conducted more easily at the system level.

The performance qualification test of the HPLC system uses a method with a well-characterized analyte mixture, column, and mobile phase. It incorporates type of measurements from the system suitability section of the general chromatography Chapter ⟨621⟩ in the *U.S. Pharmacopeia* [12]. In the end of the process proper documentation is archived.

## 2 MODES OF HPLC

There are various modes of operation of HPLC. The mechanism of interaction of the solutes with the stationary phases determines the classification of the mode of liquid chromatography. Table 1 summarizes the variety of modes of liquid chromatography, of which reversed phase stands out as the most widely used mode in HPLC, therefore, the discussion will elaborate on this mode.

### 2.1 Reversed Phase [13]

Reversed phase liquid chromatography (RPLC) is considered as the method of choice for the analysis of pharmaceutical compounds for several reasons, such as its compatibility with aqueous and organic solutions as well as with different detection systems and its high consistency and repeatability. Sensitive and accurate RPLC analysis, whether in the pharmaceutical or bioanalytical field, necessitates the use of stationary phases which give symmetrical and efficient peaks. Therefore, manufacturers of stationary phases are continuously improving and introducing new RPLC products, and the selection of various types of reversed phase stationary phases is high. The needs for consistency as well as the globalization of the pharmaceutical companies require that the methods will be transferred from site to site, using either the same column brands or their equivalents. Therefore, an extensive categorization or characterization of the rich selection of stationary phases has been done in recent years [14–21].

The stationary phase in the reversed phase chromatographic columns is a hydrophobic support that is consisted mainly of porous particles of silica gel in various

**TABLE 1 Summarizes the Most Abundant Modes of Chromatography in Pharmaceutical Analysis**

| Mode | Normal phase | Reversed phase | Ion exchange | Chiral | Affinity | Size exclusion |
|---|---|---|---|---|---|---|
| Stationary phases chemistry | Polar-hydrophilic | Non-polar-lipophilic | Ion-bonding | Chiral recognition | Bioaffinity | Sieving by size |
| Typical stationary phases | Silica, alumina | Alkylated silica, mostly C18 | Ionic functional groups on silica or polymer | Chiral groups on silica surfaces | Either substrates or biomolecules, | Gel type polymers |
| Typical mobile phase | Hexane, isopropa-nol. methylene chloride | Water, methanol, acetonitrile, buffers, ion pairing agents | Water, buffers, acid, base | Two modes: aqueous and non-aqueous | Water, buffers | Two modes: aqueous and non-aqueous |
| Typical solutes | Fatty and oily | Almost all organic compounds | Any ion-charged compounds | Enantiomers small and large molecules | Biomolecules or their substrates | Polymers: synthetic or biological |

Reversed phase chromatography is by far the most widely used mode of chromatography.

***FIGURE 2*** *The surface of reversed phase stationary phases.*

shapes (spheric or irregular) at various diameters (1.8, 3, 5, 7, 10 μM, etc.) at various pore sizes (such as 60, 100, 120, 300). The surface of these particles is covered with various chemical entities, such as various hydrocarbons (C1, C6, C4, C8, C18, etc.) as can be seen in Fig. 2. There are also hydrophobic polymeric supports that are used as stationary phases when there is an extreme pH in the mobile phase. In most of the methods used currently to separate medicinal materials, C18 columns are used, which sometimes are called ODS (octedecylsilane) or RP-18.

The more hydrophobic are the sample components the longer they stay in the column thus they are separated. The mobile phases are mixtures of water and organic polar solvents mostly methanol and acetonitrile. These mixtures contain frequently additives such as acetate, phosphate, citrate, and/or ion-pairing substances, which are surface active substances such as alkylamines as ion-pairing of anions or alkylsulfonates, ion-pairing of cations. The purpose of using such additives is to enhance efficiency and/or selectivity of the separation, mostly due to control of their retention.

The parameters that govern the retention in reversed phase systems are the following:

A. The chemical nature of the stationary phase surface [22–27].
B. The type of solvents that compose the mobile phase and their ratio [28].
C. The pH and ionic strength and additives of the mobile phase [23,29].

When the effect of these parameters on the retention of the solutes is understood it is possible to manipulate them to enhance selectivity.

***2.1.1 The Chemical Nature of the Stationary Phase [16]*** The surface of the stationary phase is described in Fig. 2. The chemical nature is determined by

the size and chemistry of hydrocarbon bonded on the silica gel surface, its bonding density (units of μmole/$m^2$), and the purity and quality of the silica gel support. As a rule, the more carbons in a bonded hydrocarbon the more it retains organic solutes (as long as similar % coverage is compared). The higher the bonding density the longer the organic solutes are retained. A column is considered relatively hydrophobic if its bonding density exceeds 3 μmole/$m^2$.

Very important modifiers of the stationary phase's surface are surface-active substances used as mobile phase's additives, acting as ion-pair reagents. These are substances such as tri-ethylamine or tetrabutylamine or hexyl, heptyl, octyl sulfonate. They are distributed between the mobile phase and the hydrophobic surface and cover it with either positive (alkylamines) or negative (alkylsulfonates) charges. This change of the surface into charged surface affects the retention significantly, especially on charged species in the sample [30].

***2.1.2 Composition of the Mobile Phase*** As a rule, the weakest solvent in reversed phase is the most polar one, water. The other polar organic solvents are considered stronger solvents, where the order of solvent strength follows more or less their dielectric properties or polarity. The less polar the solvent added to the mobile phase, the stronger it gets, shortening the retention times.

***2.1.3 PH and Ionic Strength of the Mobile Phase*** When the samples contain solutes of ionizable functional groups, such as amines, carboxyls, phosphates, phosphonates, sulfates, and sulfonates, it is possible to control their ionization degree with the help of buffers in the mobile phase. As a rule, the change of an ionizable molecule to an ion makes it more polar and less available to the stationary phase. For example, increasing the pH of the mobile phase above 4–5, which is the typical p$K_a$ of carboxyl groups, reduces the retention of carboxyl containing compounds. On the other hand, substances that contain amines whose p$K_a$ is around 8 will retain longer when the pH will be above 8. In most of the traditional silica-gel based stationary phases it is not possible to increase the mobile phase's pH above 8 due to hydrolysis of the silica gel. During the 2000s there have been developed extended pH stationary phases [31,32]

## 3 HPLC THEORY: SYSTEM SUITABILITY PARAMETERS

High performance liquid chromatography is defined as a separation of mixtures of compounds due to differences in their distribution equilibrium between two phases, the stationary phase packed inside columns and the mobile phase, delivered through the columns by high pressure pumps. Components whose distribution into the stationary phase is higher, are retained longer, and get separated from those with lower distribution into the stationary phase. The theoretical and practical foundations of this method were laid down at the end of 1960s and at the beginning of 1970s. The theory of chromatography has been used as the basis for *System Suitability* tests, which are set of quantitative criteria that test the suitability of the chromatographic

system to identify and quantify drug-related samples by HPLC at any step of the pharmaceutical analysis.

## 3.1 Retention Time ($t_R$), CAPACITY FACTOR k′, AND RELATIVE RETENTION TIME (RRT)

The time elapsed between the injection of the sample components into the column and their detection is known as the retention time ($t_R$). The retention time is longer when the solute has higher affinity to the stationary phase due to its chemical nature. For example, in reverse phase chromatography, the more lypophilic compounds are retained longer. Therefore, the retention time is a property of the analyte that can be used for its identification.

A non-retained substance passes through the column at a time $t_0$, called the void time. The *Retention Factor* or *Capacity Factor* $k'$ of an analyte is measured experimentally as shown in Fig. 3 and Eq. 1:

$$k' = \frac{t_R - t_0}{t_0} \tag{1a}$$

The *Capacity Factor* describes the thermodynamic basis of the separation and its definition is the ratio of the amounts of the solute at the stationary and mobile phases within the analyte band inside the chromatographic column:

$$k' = \frac{C_s}{C_m}\Phi \tag{1b}$$

***FIGURE 3*** *Example of capacity factor calculation in LC. In this case* $t_R = 0.739$, $t_0 = 0.17$, therefore $k' = (0.739 - 0.176)/0.176 = 3.20$.

where $C_s$ is the concentration of the solute at the stationary phase and $C_m$ is its concentration at the mobile phase and $\Phi$ is the ratio of the stationary and mobile phase volumes all within the chromatographic band.

The *Retention Factor* (Eq. 1a) is used to compare the retention of a solute between two chromatographic systems, normalizing it to the column's geometry and system flow rate. The need to determine the void time can be tricky sometimes, due to the instability of the elution time of the void time marker, $t_0$, therefore, when the chromatogram is complex in nature, and one known component is always present at a certain retention time, it can be used as a retention marker for other peaks. In such cases, the ratio between the retention time of any peak in the chromatogram and the retention time of the marker is used ($t_{R(Peak)}/t_{R(Marker)}$) and referred to as the *relative retention time* (RRT). RRT is also used instead of the capacity ratio for the identification of the analyte as well as to compare its extent of retention in two different chromatographic systems.

## 3.2 Efficiency: Plate Count N and Peak Capacity $P_c$

Figure 4 describes a chromatogram with four peaks and a detected void peak. The parameters of the system suitability are displayed in the inserted table. The sharpness of a peak relative to its retention time is a measure of the system's efficiency, calculated as $N$, plate count. Band-broadening phenomena in the column such as eddy diffusion, molecular diffusion, mass-transfer kinetics, and extra-column effects reduce the efficiency of the separation [33]. The sharpness of a peak is relevant to the limit of detection and limit of quantification of the chromatographic system. The

| | Name | RT | Area (µV*sec) | Height (µV) | k ' | Signal To Noise | USP Plate Count | USP Resolution | USP Tailing |
|---|---|---|---|---|---|---|---|---|---|
| 1 | Void | 0. 665 | 1780 | 725 | 0. 00 | 32 | 1742 | | 1. 28 |
| 2 | Peak 1 | 1. 279 | 459570 | 153161 | 0. 92 | 6747 | 4191 | 8. 34 | 1. 36 |
| 3 | Peak 2 | 2. 818 | 238940 | 59382 | 3. 24 | 2616 | 11320 | 16. 30 | 1. 21 |
| 4 | Peak 3 | 3. 606 | 41372 | 8776 | 4. 42 | 387 | 13266 | 6. 69 | 1. 17 |
| 5 | Peak 4 | 5. 120 | 26102 | 4277 | 6. 70 | 188 | 15902 | 10. 34 | 1. 11 |

***FIGURE 4*** *Example of a system suitability run's result.*

***FIGURE 5*** *System suitability measurements on a single peak.*

sharper the peak for a specific area, the better is its signal-to-noise; hence the system is capable of detecting lower concentrations. Therefore, the efficiency of the chromatographic system must be established by the system suitability test before the analysis of low concentrations that requires high sensitivity of the system, such as the analysis of drug impurities and degradation products.

The efficiency of the separation is determined by the plate count $N$ when working at isocratic conditions, whereas it is usually measured by peak capacity $P_c$ when working at gradient conditions [34]. The following equation for the plate count is used by the United States Pharmacopoeia (USP) to calculate $N$ (see Fig. 5):

$$N = 16 \times \left( \frac{t_R}{w_{(\text{Baseline})}} \right)^2 \tag{2}$$

where $w$ is measured from the baseline peak width calculated using lines tangent to the peak width at 50% height (see Fig. 5). European and Japanese Pharmacopeias use the peak width at 50% of the peak height (see Fig. 5), hence the equation becomes

$$N = 5.54 \times \left( \frac{t_R}{w_{(50\%)}} \right)^2 \tag{3}$$

*Peak capacity* $P_c$ is defined as number of peaks that can be separated within a retention window for a specific pre-determined resolution. In other words, it is the runtime measured in peak width units [34]. It is assumed that peaks occur over the

gradient chromatogram. Therefore, *peak capacity* can be calculated from the peak widths $w$ in the chromatogram as follows:

$$1 + \frac{t_g}{(1/n)\sum_{1}^{n} w} \tag{4}$$

where $n$ is the number of peaks at the segment of the gradient selected for the calculation, $t_g$. Thus peak capacity can be simply the gradient run time divided by the average peak width. The sharper the peaks the higher is the peak capacity, hence the system should be able to resolve more peaks at the selected run time as well as detect lower concentrations.

Another measure of the column's chromatographic efficiency is the *height equivalent to theoretical plate* (HETP) which is calculated from the following equation:

$$\text{HETP} = (L/N) \tag{5}$$

where $L$ is column length and $N$ is the plate count. HETP is measured in micrometer. For example, in the peak of Fig. 5 the column length was 100 mm (0.1 m) therefore HETP was 8.8 μm at the flow rate of the experiment.

The behavior of HETP as function of linear velocity has been described by various equations [35]. It is frequently called "The Van-Deemter curve," and it is frequently used to describe and characterize various chromatographic stationary phases' performance and compare them to each other [36–39]. The lower are the values of HETP, the more efficient is the chromatographic system, enabling the detection of lower concentrations due to the enhanced signal-to-noise ratio of all the peaks in the chromatogram.

### 3.3 Peak Asymmetry Factor, $A_f$ AND TAILING FACTOR T

The chromatographic peak is assumed to have a Gaussian shape under ideal conditions, describing normal distribution of the velocity of the molecules populating the peak zone migrating through the stationary phase inside the column. Any deviation from the normal distribution indicates non-ideality of the distribution and the migration process, therefore might jeopardize the integrity of the peak's integration, reducing the accuracy of the quantitation. This is the reason why USP Tailing is a peak's parameter almost always measured in the system suitability step of the analysis.

The deviation from symmetry is measured by the *Asymmetry Factor*, $A_f$ or *Tailing Factor T*. The calculation of *Asymmetry Factor*, $A_f$, is described by the following equation:

$$A_f = \frac{A_{(10\%h)}}{B_{(10\%h)}} \tag{6}$$

where $A$ and $B$ are sections in the horizontal line parallel to the baseline, drawn at 10% of the peak height as shown in Fig. 5.

The calculation of *Tailing Factor*, $T$, which is more widely used in the pharmaceutical industry, as suggested by the pharmacopeias, is described by the following equation:

$$T = \frac{A_{(5\%\mathrm{h})} + B_{(5\%\mathrm{h})}}{2A_{(5\%\mathrm{h})}} \tag{7}$$

where $A$ and $B$ are sections in the horizontal line parallel to the baseline, drawn at 5% of the peak height, as also shown in Fig. 5. The USP suggests that *Tailing Factor* should be in the range of 0.5 up to 2 to assure a precise and accurate quantitative measurement. The peaks in Figs. 4 and 5 have a Tailing Factor within the USP requirements.

### 3.4 Selectivity Factor α and Resolution Factor Rs

The separation is a function of the thermodynamics of the system. Substances are separated in a chromatographic column when their rate of migration differs, due to their different distribution between the stationary and mobile phases. The *Selectivity Factor, a*, and *Resolution Factor, Rs*, measure the extent of separation between two adjacent peaks. The *Selectivity Factor* accounts only for the ratio of the *Retention Factors, k′*, of the two peaks ($k'_2/k'_1$), whereas the *Resolution Factor, Rs*, accounts for the difference between the retention times of the two peaks relative to their width.

The equation that describes the experimental measurement of the *Resolution Factor, Rs*, is as follows:

$$Rs = \frac{t_{\mathrm{R}(2)} - t_{\mathrm{R}(1)}}{0.5(w_2 + w_1)} \tag{8}$$

where $t_{\mathrm{R}}$ is the retention time of peaks 1 and 2 respectively and $w$ is their respective peak width at the tangents' baseline (see Fig. 5). According to the pharmacopeias *Rs* should be above 1.5 for an accurate quantitative measurement. Figure 4 shows that the resolution measured between every two adjacent peaks in the chromatogram was above 1.5, therefore, it was above the minimum required.

The resolution is a critical value when working with complex samples such as drug impurities and degradation products, or when the formulation is complex and excipients might interfere with the quantitative measurements. Therefore, it is an essential part of the system suitability measurement stage before the quantitative work of these types of samples.

The sample used for the measurements of *Rs* during the system suitability runs is sometimes called *Resolution Solution*, as can be seen in Fig. 4 It usually contains the components that are the most difficult to resolve.

The theoretical description of the *Resolution Factor Rs* equation is shown in Eq. 9. It includes some of the above parameters, the plate count $N$, the selectivity $a$, and the average of the two peaks' capacity factors $k'$:

$$Rs = \frac{\sqrt{N}}{4}\left(\frac{\alpha-1}{\alpha}\right)\left(\frac{k'_{\text{ave}}}{k'_{\text{ave}}+1}\right) \tag{9}$$

It can be clearly seen from this equation that the plate count is the most effecting parameter in the increase of the chromatographic resolution. Since the plate count increases with the reduction in particle diameter, it explains the reduction in particle diameter of the stationary phase material during the last three decades of HPLC. This is also the rational behind the recent trend in HPLC, the use of sub-2 μm particle columns and the development of a specially design of ultra performance HPLC systems to accommodate such columns [36,40–42].

## 4 THE ROLE OF HPLC IN DRUG ANALYSIS

The most characteristic feature of the development in the methodology of pharmaceutical and biomedical analysis during the past 25 years is that HPLC became undoubtedly the most important analytical method for the identification and quantification of drugs, either in their active pharmaceutical ingredient (API) or in their formulations during the process of their discovery, development, and manufacturing [43–50].

Figure 6 summarizes the various stages of the pharmaceutical streamline of drug discovery, development, and manufacturing. Drug development starts with the discovery of a molecule with a therapeutic value [51,52]. This can be done by high throughput screening during which separations by fast or ultra-fast HPLC are performed [53]. At the discovery stage there can be also characterizing synthetic or natural products [54–57]. Drug metabolism and pharmacokinetics (DMPK) is the step where the candidate compounds for drug are tested for their metabolism and pharmacokinetics. The studies involve use of LC–MS or LC–MS/MS [58–62].

The next stage is the development stage, where HPLC is used to characterize products of the chemical synthesis, by analyzing the API, their impurities [63,64], and/or degradation products generated by accelerated aging [65,66]. The development of formulation requires also studies of the dissolution properties of solid dosage forms as well as assays of the pharmaceutical formulations [67]. Method for the verification of system's cleanliness during the manufacturing process is developed and used at this stage [68]. All the HPLC methods that have been finalized at the developmental stage are validated and transferred to the manufacturing laboratories for a quality control analysis [69–76].

### 4.1 The Discovery Stage

The goal in the discovery stage of drug development is to discover a new, safe and active chemical entity (NCE) that will become medication for diseases. During the

***FIGURE 6*** *Steps in a drug development and manufacturing in the pharmaceutical industry.*

last decade parallel synthesis of potential lead compounds, using combinatorial chemistry, has been done [51,77–79]. The large numbers of products created by the combinatorial chemistry are then identified by fast LC–MS methods and screened by *in vitro* bioassays and/or pharmacological or chemical tests to allow a selection of a few chosen drug candidates [53,59,61,80,81].

When the lead compounds are selected, the next steps involve pharmacological studies. Due to its high sensitivity and selectivity, HPLC coupled with tandem mass spectrometry (MS), HPLC–MS/MS, has become the predominant method in bioassays, and pharmacokinetic and metabolic studies [58–62,82]. In addition, another new development in this field has been the introduction of column's packing with ultra-fine particles ($<2\,\mu m$) enabling short columns to be used (5 cm or less) and rapid analyses (e.g., 5 min or even less than 1 min) to be carried out by UPLC (ultra performance liquid chromatography) [36,40–42,53,83–88].

## 4.2 Bioanalytical Studies

The support of bioanalytical testing includes quantitation of a target compound in various biological matrices as part of pre-clinical lead optimization by measurement its adsorption, distribution, metabolism, and excretion (ADME) [53,58–62,84,89–91]. The samples are physiological fluids such as plasma, serum, tissue extracts, and urine, typically from experimental animals or human subjects [70,84,92]. During the last decade conventional HPLC methods using fluorescence or electrochemical detection, following an elaborate sample clean-up, have been replaced by HPLC–MS/MS or U-HPLC–MS/MS methodologies. Sample clean-up is simpler and more automated

and usually involves protein precipitation and/or solid phase extraction techniques [92].

The chromatographic method is typically very rapid, gradient, or isocratic, using small columns' dimensions, such as $2.1 \times 50\,mm^2$ or less. A trace of a typically stable daughter ion signal, obtained from the fragmentation of a parent analyte is used for the detection and quantitation. Such a mode is called MRM (multiple reaction monitoring) or SRM (selective reaction monitoring), which is more stable, sensitive, and selective than either the fluorescence or electrochemical signal. Samples are usually ordered in 96 microplates for higher throughput and minimum variability of the sample vials [93]. An internal standard is used typically to minimize assay variability, due to the clean-up stage and MS/MS response, which is still less stable than UV response [94].

## 4.3 The Development Stage

The development stage is the part during which some of the HPLC methods that will be used during the subsequent manufacturing stages are developed, validated, and then transferred. The methods involve identification of the drug substance, its assay, impurities, stability, the dosage form content uniformity, dissolution, and so on. The methods are validated first, and then transferred to the quality control laboratories. Details are given in Section 3.3.

## 4.4 Method Validation

All HPLC methods used for the development of pharmaceuticals and for the determination of their quality have to be validated. In cases whereby methods from the Pharmacopeia's are used, it is not necessary to evaluate their suitability, provided that the analyses are conducted strictly according to the methods' intended use. In most other cases, especially in cases of modification of the drug composition, the scheme of synthesis or the analytical procedure, it is necessary to re-evaluate the suitability of the HPLC method to its new intended use [95].

The parameters tested throughout the method validation as defined by the ICH, USP and FDA, and other health organizations [95–97] are the following: specificity or selectivity, precision (repeatability, intermediate precision, reproducibility, or ruggedness), accuracy or trueness or bias, linearity range, limit of detection, limit of quantitation, and robustness.

The terms *selectivity* and *specificity* are often used interchangeably. The USP monograph defines selectivity of an analytical method as its ability to measure accurately an analyte in the presence of interference, such as synthetic precursors, excipients, enantiomers, and known (or likely) degradation products that might be present in the sample matrix. A method whose selectivity is verified is a "Stability Indicating Method (SIM)," for details please see Section 3.3.

*Precision* of a method is measured by injecting a series of standards and measuring the variability of the quantitative results. The measured standard deviation can be subdivided into three categories: repeatability, intermediate precision, and reproducibility (or ruggedness):

- Repeatability is obtained when one operator using one system over a relatively short time-span carries out the analysis in one laboratory. At least five or six determinations of three different matrices at two or three different concentrations should be done and the relative standard deviation calculated.
- Intermediate precision is a term that has been defined by ICH [96] as the long-term variability of the measurement process and is determined by comparing the results of a method run within a single laboratory over a number of weeks. A method's intermediate precision may reflect discrepancies in results obtained by different operators, from different instruments, with standards and reagents from different suppliers, with columns from different batches or a combination of these. Objective of intermediate precision validation is to verify that in the same laboratory the method will provide the same results once the development phase is over.
- Reproducibility (or reggedness), as defined by ICH represents the precision obtained between laboratories. The objective is to verify that the method will provide the same results in different laboratories, preparing it for the transfer to other sites.

Typical variations affecting a method's reproducibility are:

- Differences in room temperature and humidity.
- Operators with different experience and thoroughness.
- Equipment with different characteristics, such as delay volume of an HPLC system or injection modes.
- Variations in material and instrument conditions, for example different protocols of the mobile phases preparation; changes in composition, pH, flow rate of mobile phase.
- Equipment and consumables of different ages.
- Columns from different suppliers or different batches.
- Solvents, reagents, and other material with different quality.

*Accuracy* of an analytical method is the extent to which test results are close to their true value. It is measured from the result of a quantitative determination of a well-characterized known sample. The amount measured is compared to the known amount.

*Linearity* of an analytical method is determined by a series of three to six injections of five or more standards whose concentration's span is 80–120% of the expected concentration range. The response should be proportional to the concentrations of the analytes, directly or by means of a well-defined mathematical calculation. A linear regression equation, applied to the results, should have an intercept not significantly different from zero. If a significant non-zero intercept is obtained, it should be demonstrated that there is no effect on the accuracy of the method. The range of concentrations that an analytical method can be implemented on is the interval between the upper and lower levels (including these levels) that have

been demonstrated to have the appropriate precision, accuracy, and linearity. The range is normally expressed in the same units of the test results (e.g., percentage, parts per million) obtained by the analytical method.

*Limit of detection*: It is the lowest concentration of analyte in a sample that can be detected but not necessarily quantified. In chromatography the detection limit is the injected amount that results in a peak height of at least two or three times as high as the baseline noise level.

*Limit of quantitation*: It is the minimum injected amount that gives precise measurements. In chromatography it typically requires peak heights of 10–20 times higher than baseline noise at precision of <10–15% RSD between results.

*Robustness* of analytical method is a measure of its capacity to remain unaffected by small but deliberate variations in method parameters and provides an indication of its reliability during normal usage.

Once validated, the methods are ready for transfer to the manufacturing quality control laboratories. Method transfer is the last stage of the validation, whereby results are tested on both the development and the manufacturing sites. Technology transfer is especially important in the era of increasing globalization of the pharmaceutical companies [69,74,98].

## 4.5 The Manufacturing Stage

***4.5.1 Identification*** The identification test by HPLC is aimed to confirm the identity of the active pharmaceutical ingredient inside the samples of either drug substance or drug product. Two independent tests are needed, for example, one chromatographic and one spectroscopic. Therefore, a chromatographic run with a diode-array or MS detector will provide both parameters, the retention time in the chromatogram and the spectrum UV or MS of the eluting peak, matched against a known standard [99–103].

***4.5.2 Assay and Content Uniformity*** An assay of a sample containing either drug substance or drug product quantitatively measures the actual amount of the active ingredient compared to that expected in the drug substance assay, whereas in drug products the actual amount measured is verified against the label claim. The official assays are described in the pharmacopeias, such as United State's (USP) [12].

When a solid dosage form such as tablet or capsule is tested, it is usually requested to sample a composite of 10–20 units to avoid tablet-to-tablet variations. The API is extracted from the dosage form in the simplest most effective way to optimize recovery. A portion of the composite group, equivalent to an average unit dosage form weight is taken for the analysis [104,105]. Typical specifications for most drug products are 90–110% of the label claim.

A content uniformity test is similar to the drug product assay but an individual solid dosage form is tested instead of a pool of the tablets/capsules as in the assay tests. Ten tablets are taken for the assay, and if the specifications of uniformity are not met, more tablets are taken. The typical calculations are made according to a scheme given by the USP [106].

Most assays and content uniformity methods involve the use of UV detection, no extensive sample preparation is needed, the standards are usually external and highly qualified [107], typical specifications can be 98–102% purity on dried basis. Specifications for system suitability were determined by the pharmacopeia [108].

***4.5.3 Dissolution*** Drug absorption from a solid dosage form after oral administration depends on its release from the drug product, its dissolution, or solubilization under physiological conditions, and the permeability across the gastrointestinal tract. Because of the critical nature of the first two of these steps, *in vitro* dissolution may be relevant to the prediction of *in vivo* performance. Based on this general consideration, *in vitro* dissolution tests for solid oral dosage forms, such as tablets and capsules, are used to (1) assess the lot-to-lot quality of a drug product; (2) guide the developers of new formulations; and (3) ensure continuing product quality and performance after certain changes, such as changes in the formulation, the manufacturing process, the site of manufacture, and the scale-up of the manufacturing process.

The dissolution test measures the release of the drug substance from its dosage form into a dissolution bath under standardized conditions, specified by the pharmacopeias [67,109–116]. The US Food and Drug Administration issued a guidance for the industry in 1997 [95]. The tests are performed usually on two types of bath apparatus, Type I is a basket method and Type II is a paddle method. Since most drugs have absorption in the UV–VIS range, their dissolution has been traditionally measured by UV–VIS spectrometry and HPLC–UV. The advantage of HPLC over UV spectrometry is its separation capabilities, providing higher specificity and sensitivity as well as its applicability in formulations with multiple API's or very low dose.

The method is typically isocratic and very short to accommodate for the high throughput needed, therefore the columns are typically very short. The sample is collected from the dissolution apparatus at certain time intervals, designed according to its release pattern, and the released substance must follow strict release specifications. A dissolution profile of Prednisone tablets, used to calibrate a dissolution bath, is shown in Fig. 7.

***4.5.4 Drug Impurities*** Many potential impurities result from the API manufacturing process, including starting materials, isomers, intermediates, reagents, solvents, catalysts, and reaction by-products [117]; therefore, impurity control is essential during the process of drug development and manufacturing. HPLC has become the major technique in this process [63,64,118–126].

The quality of the API starting material is tested by HPLC to qualify it for the production of API that meets its specifications, as its impurities can be carried through directly or can participate in the reaction chemistry to produce significant impurities in the final product, the API. It is likely that different synthetic routes that produce different impurities may be used by different suppliers. In some cases, the synthetic route is not disclosed to the API producer; therefore, a thorough investigation of impurities in starting materials must then be conducted. This investigation includes HPLC method development, a search for potential impurities, as well as identification

***FIGURE 7*** *Dissolution profile of Prednisone tablets.*

of significant unknown impurities and assessment of their impact on the API quality. Results of such an investigation are used to set specifications for the starting material that will assure its suitability for use in API production [117]. Similar considerations apply to the drug product. Strict international regulatory requirements have been enforced for several years as outlined in the International Conference on Harmonization (ICH) Guidelines Q3A(R), Q3B(R), and Q3C [127–129].

A typical method for the measurement of impurities can be rather complicated and difficult, as it requires high resolution to distinguish between closely related compounds, high sensitivity to detect low concentrations of the impurities, and wide dynamic range of the system to be able to detect the major components as well as their impurities and degradation products in one run. The method should have the following important attributes:

- First of all the sample preparation should be as simple as possible, to stay true to the original composition of the sample, either a drug substance or a drug product, not to lose or create an impurity during this process.
- The chromatographic separation should be optimal, to resolve all the impurities from each other and from the API's.
- The quantitative protocol involves frequently a calibration, using well-characterized impurities standards, and/or calibration against a diluted standard of the main API, taking into account their relative response factor. Sometimes the impurities are just normalized against the main peak using % area.
- The main peak is frequently at overloaded concentrations and if the normalization method of % area is used, its inclusion within the linear range should be established.

- According to the ICH guidelines and depending on the daily dose, the quantification limits of unspecified impurities can get as low as 0.05–0.1% of the main peaks. Specified known impurities can be reported at higher levels, provided their toxicology was determined.
- Method validation must include the establishment of limit of detection (to be used for rejection of small peaks) and limit of quantitation (which is used as the minimum value for linearity range specifications).
- There is a substantial effort to ensure that the main peak does not hide a co-eluted impurity by measuring peak purity (see next section).

Most methods for impurities involve a gradient of the mobile phase, to be able to resolve a complex mixture of all compounds in one run, polar as well as non-polar. In recent years, the mobile phase is programmed to be MS compatible, i.e., the buffers used are volatile, so that impurities can be identified by LC–MS at the developmental and verification stages of the analysis.

***4.5.5 Drug Stability*** Stability testing of drug substance or product is performed to ensure that their quality does not vary with time under the influence of a variety of environmental factors such as temperature, humidity, and light [130]. In addition, stability studies are typically done using HPLC methods, to determine the re-test period of a drug substance and/or the shelf life of the drug product as well as its recommended storage conditions. Guidelines to the industry are given by the ICH [129].

An HPLC method used for stability studies is termed SIM [65,66,131–137]. According to the FDA guidelines, an SIM is defined as a validated analytical procedure that accurately and precisely measures active ingredients (drug substance or drug product) free from potential interferences like degradation products, process impurities, excipients, or other potential impurities. FDA recommends that all assay procedures for stability studies will be stability indicating. A typical chromatogram of a drug substance in a stability program is shown in Fig. 8. The results are shown in Table 2.

The HPLC system used for stability indicating methods development and validation must contain 3D data capabilities such as diode-array detectors and/or mass spectrometers, to be able to detect spectral non-homogeneity within the chromatographic peaks [99–101,138]. Figures 9 and 10 present 3D data obtained by photo-diode array and mass detectors respectively. The modern UV–VIS diode-array technology is capable of evaluating specificity of the method to the analyte in question by collecting spectrum at each acquisition data point across a peak, and through software manipulations each such spectrum is compared to a reference spectrum, to determine spectral homogeneity, hence determine peak purity. Figures 11 and 12 demonstrate graphically how the software collects spectra from various points across the peaks to determine their similarity. We can see in this example that there is a minor interference only in Peak 2, as its UV spectra do not perfectly overlap. The mass spectrometer's spectra in Fig. 12 were collected by combining spectra across the peak.

***FIGURE 8*** *A chromatogram of an API sample at a stability program. Detection: UV at 286 nm, isocratic run (70:30 water:acetonitrile with 0.1% TFA); flow rate = 1 mL/min. Results are shown in Table 2.*

The spectra confirm the suspicion and indicate the co-eluting interference in Peak 2; however, they also indicate that there is an interference in Peak 1 as well, although the UV spectra could not detect it!

Since 2006 it has been recommended that a peak purity test, based upon photodiode-array (PDA) detection, will also be based on MS whenever possible, to be more definite [99,101,138]. As already was noticed in Figs. and discussed in the previous section, the spectroscopic data obtained by the MS detector is much more reliable in evaluating the interferences co-eluting with the major chromatogram's peaks.

As noticed in Figs. 11 and 12, the UV–VIS diode-array detectors might be limited in evaluating peak purity in cases whereby the UV–VIS spectra of the main peak and its impurities are similar and/or the noise in the system is relatively high, masking the co-eluting impurities and degradants.

Three conditions must be fulfilled for the major components and their related compounds to be effective in the peak purity determination by diode-array detectors:

- They must have a UV chromophore, or some absorbance in the wavelength range selected.

**TABLE 2 Results from the HPLC Run Shown in Fig. 8 of an API After 3 Months Stability Test in Heat**

| Name | RT | Area | % Area | RRT | Signal to noise | $k'$ | USP resolution | USP plate count |

***FIGURE 9*** *3-Dimensional plot of a chromatographic run of three sulfa drugs, using a diode-array detector.*

- There should be a minimal degree of chromatographic resolution between the main peak and its co-eluting impurities (chromatographic resolution between 0.3 and 0.7).
- There must be some degree of spectral difference between the analyte peak and the co-eluting impurity.

***FIGURE 10*** *3-Dimentional plot of the same three sulfa drugs as in Fig. 9, using a mass spectrometer detector.*

***FIGURE 11*** *UV chromatogram at 270 nm of three sulfa drugs shown in Fig. 9, and a plot of UV spectra collected from each peak's apex, inflection, and two offset points, to demonstrate comparison of spectra collected at various points across the peak.*

***FIGURE 12*** *SIR chromatograms of the same sulfa drugs as in Fig. 10 and their corresponding mass spectra, obtained by combining spectra across the entire peak.*

Stress testing is carried out on a single batch of the drug substance and/or the drug product, using forced degradation of the drug substance [65]. The results of such studies can help identify the likely degradation products, which can in turn help establish the degradation pathways and the chemical stability of the molecule and to validate the stability indicating capabilities of the analytical procedures used.

The nature of the stress testing will depend on the individual drug substance and the type of drug product involved. It usually includes the effect of temperatures, humidity, oxidation, and photolysis on the drug substance. The testing also evaluates the vulnerability of the drug substance to hydrolysis across a wide range of pH values when in solution or suspension. Photo-stability testing is also an integral part of a stress testing [65,66,124,129,131,135,137].

***4.5.6 Cleaning Validation*** Cleaning validation tests are performed to assure the cleanliness of the pharmaceutical manufacturing equipment, such as blender, tablet press, and so on. There are strict specifications for the maximum allowable amounts of the residues, according to their toxicology and daily dosage [139]. The analytical methods must be extremely sensitive, to be able to track the residues of the analytes, their degradants, or impurities, other contaminations or the cleaning reagents themselves [85,140–147]. The methods must be very sensitive and short, as the entire manufacturing process depends on the approval of the cleanliness of apparatus. Due to the enhanced sensitivity as well as speed of analysis, the use of ultra performance liquid chromatography has immediately adopted in the cleaning validation tests [85].

***4.5.7 In-Process Control*** In-process control method monitors the progress in the manufacturing of an active pharmaceutical ingredient or its formulation. HPLC is frequently employed for the in-process assay of active pharmaceutical ingredient synthesis [68,72,148,149]. The results signal the production chemist/pharmacist whether to proceed with a subsequent unit operation. The decision about whether to use an in-process control test in a manufacturing is established during process development and is based on scientific judgment. In recent years, the FDA issued a recommendations for process analytical technology (PAT) [150]. The guidance intended to describe a regulatory framework that will encourage the voluntary development and implementation of innovative pharmaceutical development, manufacturing, and quality assurance. The new LC ultra performance/rapid technologies are emerging as the technology of choice for the in-process control assay due to their extended efficiency, sensitivity, and speed of the analysis [68,151].

## 5 SPECIAL TOPICS

### 5.1 Ultra High Performance Liquid Chromatography

In order to enhance chromatographic performances in terms of efficiency and speed, LC has recently evolved thanks to the development of short columns packed with

small particles (sub-2 μm), working at high pressures (Above 1000 bar) [40,152–155]. This approach has been described 30 years ago according to the fundamental chromatographic equations [156]. However, systems and columns compatible with such high pressures have been introduced into the market since 2004 only. Advantages of small particles working at high pressure have been vividly discussed in the literature, in terms of sensitivity, efficiency, resolution, and analysis time, showing how systems working at a maximum pressure of 1000 bar give reliable and reproducible results. The implementation of the new technology in the pharmaceutical and life sciences is soaring and it becomes the next benchmark technology for the near future [41,42,84,85,152,157].

There are important experimental parameters one should be aware of while reducing the particle size [158]. First and foremost is the column pressure. Equation 10 shows the dependence of column head pressure on a number of experimental parameters including the particle size. As can be seen in Eq. 10, the pressure is inversely proportional to the square of the particle size.

$$P = \frac{\Phi L \eta \mu}{100 \times d_p^2} \tag{10}$$

where $P$ is the pressure drop, $\Phi$ is the flow resistance parameter, $\eta$ is viscosity (mPa/s), $L$ is column length (mm), $\mu$ is the linear velocity (mm/s), and $d_p$ particle size (μm). So when the particle size is halved, the pressure goes up by a factor of 4. However, often for fast separations, the column length is also reduced, so the pressure increase is not nearly as high as one would expect, because pressure is proportional to column length.

If longer columns such as 100 or 150 mm are required to achieve higher resolution and sensitivity, then higher pressure pumps are required. Currently, there are commercial HPLC systems with upper pressure limits as high as 15 000 psi. It should be noted that the total pressure that the HPLC system experiences is the sum of the column and the instrument backpressures. The latter results when small internal diameter capillaries are used in the flow paths to reduce extra-column effects and minimize the gradient delay volume [33]. As the flow rate increases, the back pressure due to these capillaries increases proportionally.

An experimental parameter that requires the most careful consideration when reducing the column length and especially internal diameter is the extra-column band broadening. Some of the modern ultra-fast LC columns are only 1.5-cm long with an internal diameter of 2.1 mm. Such a column has a total void volume of around 33 μL. Many conventional HPLC instruments were developed for typical 15 and 25 cm × 4.6 mm analytical columns, whose void volumes are ~1.6 and ~2.6 mL, respectively. A 1.5 cm × 2.1 mm column packed with 1.8-μm particles often produces a few microliters peaks, which requires that extra-column band broadening will be minimized to accommodate for the true advantages of these small columns. Some modern liquid chromatographs have been designed or modified to minimize the extra-column

effects [157]. For others, upgrade kits are available to modify some older HPLC instruments to work satisfactorily with sub-2-μm columns.

Some other experimental parameters that must be taken into account when running fast and ultrafast separations in LC are as follows [86,159]:

- *Detector time constant*: Peaks can be only a second or two wide when short narrow-bore columns run at high flow rates. A time constant that is too slow will make the peaks artificially broad because the detector cannot keep up with the rapidly changing signal.
- *Data sampling (acquisition) rate*: Data system needs enough data points, minimum of 20 across a peak to define the peak as proper for integration of area, determine retention time, and so on.
- *Autosampler cycle time*: Separations whose run time is less than a minute or two, throughput can be slowed down by a slow autosampler.
- *Gradient delay volume*: If the volume between the points, where the gradient forms (mixer), to the column head is too large, gradient profiles will be compromised because gradient has not reached column in time.

When transferring methods from HPLC to UPLC there is a scale-down process of the sample load, flow-rate, and gradient times [86,159]. Sample load must be reduced proportionally to the columns volumes, a typical factor can be from ~1.5 mL (4.6 × 150 mm column) to ~0.15 mL (2.1 × 100 mm column). Equation 11 describes the calculations required for such a scale-down.

$$M_{\mathrm{UPLC}} = M_{\mathrm{HPLC}} \frac{L_{\mathrm{UPLC}}}{L_{\mathrm{HPLC}}} \frac{\mathrm{ID}_{\mathrm{UPLC}}}{\mathrm{ID}_{\mathrm{HPLC}}} \tag{11}$$

where $M$ is the sample load in mg, $L$ is column's length, and ID is internal column's diameter.

It should be noted that the separation mechanisms in UPLC compared to HPLC are still the same; chromatographic principles are maintained while speed, sensitivity, and resolution is improved. This all supports easier method transfer from HPLC to UPLC and its revalidation. The main advantages are significant reduction of analysis time and flow-rates (which means also reduction in solvent consumption!), enhanced peak capacity and sensitivity, which means that complex analytical determination of pharmaceutical preparations can be accomplished much easier within a reasonable time. Moreover, time spent with new method development, optimization, and validation is significantly saved.

A typical chromatogram obtained in the UPLC system is shown in Fig. 13. A mixture of alkylphonone is chromatographed on a 2.1 × 50 $mm^2$ Acquity BEH C18 column packed with 1.7 μM particles at room temperature using a gradient of 5% MeCN to 95% Acetonitrile within 3 min at a flow rate of 0.5 mL/min. Re-equilibration time was 1.5 min and solvent consumption was 2.5 mL/run. The spectacular resolution and peak widths in such a short time are noticeable.

***FIGURE 13*** *Mixture of alkylphenones injected into waters' acquity UPLC using acquity BEH C18 2.1 × 50 mm² 1.7 μM.*

## 5.2 Preparative Chromatography

Preparative chromatography is used to isolate and purify compounds [6,73,160–166]. Typically this type of separations requires larger columns and the chromatograms generally display broader peaks, due to the increased column load. The separation is optimized for higher throughput (weight/time), then sample load is maximized on small analytical columns, and finally quantities are scaled up to the preparative column according to the desired purity and recovery.

The parameters that will govern efficiency of the preparative separation are the plate count, the capacity factor $k'$, and the selectivity between the solutes (see Section .2). As selectivity, $a$, between two adjacent peaks of interest is improved, a better separation between them at higher sample loads is obtained, getting better product purity. Mobile phase changes cause this change in selectivity, as well as selecting the appropriate stationary phase.

Peak shape is no longer a concern, only the collected product's purity. The scaling up of the mass load can be done according to the column's volume ratio as is shown in Eq. 11, but instead of ratio between UPLC and HPLC, the ratio is between the analytical column and the preparative one.

A rational approach to scaling up HPLC runs, using adsorption isotherms measurements and calculations has been described [167]. In the pharmaceutical work, preparative chromatography is used mostly to isolate drug impurities for the purpose of their identification and/or using them as working standards for impurities determination [168]. Purification of compounds during drug development and manufacturing has been done in recent years using UV in line with mass spectrometer, to achieve a mass-directed purification, whereby the mass spectrometer is used to determine the cutoff of the purified compound and direct the pure compound into its collection vessel [169].

### 5.3 Chiral Chromatography

The biological activity of chiral substances often depends upon their stereochemistry, since the living body is a highly chiral environment [170–172]. A large percentage of commercial and investigational pharmaceutical compounds are enantiomers, and many of them show significant enantioselective differences in their pharmacokinetics and pharmacodynamics. The importance of chirality of drugs has been long recognized, and the consequence of using them as racemates or as enantiomers has been frequently discussed in the pharmaceutical literature [173–175]. With increasing evidence of problems related to stereoselectivity in drug action, chiral chromatography has become the major tool in their analysis [171,173–184]. Great efforts have been devoted to the development of better methodology for enantioselective chromatography during the past two decades, and have resulted in variety of chiral stationary phases. Chiral agents were derivatized and immobilized on the surface of the support (silica gel mostly), and served as the *in situ* chiral discriminators during the chromatographic process.

The chiral stationary phases can be categorized into the following classes:

A. Chiral affinity by proteins (serum albumin, a1-acid glycoprotein, ovomucoid, and chymotrypsin) [185].
B. Stereoselective access to helical chiral polymers (derivatized or free polysaccharides) [186,187].
C. Steric interactions between p-donor p-acceptor type of chiral aromatic amide groups (Pirkle) [188].
D. Host–guest interactions inside chiral cavities (cyclodextrins, crown ethers, macrocyclic antibiotics, and imprinted polymers) [189–192].

Major developments in chiral stationary phases have led to dramatic advances in enantioselective chromatography [175]. Chromatographic enantioseparation on chiral stationary phases results from energy differences between transient diastereomeric complexes formed by the solute with the chiral agent on the surface of the chiral stationary phase interactions. These differential interactions are directly influenced by the mobile phase environment. The solvents in the mobile phase can be either normal phase, or aqueous reversed phase's [193] or polar organic [187].

During recent years the trend in the pharmaceutical manufacturing of drugs containing chiral centers is to develop them as single enantiomers rather than racemates due to the complexity of the tests and research involved in the use of racemates as API's [64].

## 6 CONCLUSION

HPLC technology has matured to the extent that almost any existing organic compound can be analyzed by an existing method that can be found in the analytical literature, such as professional journals, protocol books such as Pharmacopeia's or

AOAC manuals. The most remarkable change in the pharmacopeias in the past 25 years has been the increasing importance of HPLC technology in the analysis of all aspects of drug development and manufacturing.

## OVERVIEW

With over 14,000 papers currently in the literature, and more appearing daily, microdialysis is one of the most popular techniques for sampling biological molecules from living tissue. Dialysis, the process of sampling fluid in the *in vivo* environment, utilizes a semi-permeable membrane, allowing endogenous biological molecules to diffuse into a sample via a concentration gradient. The main focus of this chapter will be microdialysis in brain. *In vivo* brain microdialysis sampling has been critical in enhancing our understanding of the native biochemistry of important central nervous system (CNS) proteins. Additionally, brain microdialysis has been essential in revealing many physiological and molecular aspects of human brain disease. There are a multitude of other techniques available for the studying brain neurochemistry, such as positron and single photon emission tomography, biosensors (including carbon fiber microelectrodes), push–pull perfusion, and ultrafiltration. The advantages of microdialysis lie in its ability to simultaneously sample a variety of biologically relevant signaling molecules, measure basal or stimulated levels of endogenous neurotransmitters, and monitor the pharmacokinetics of exogenously administered compounds. *In vivo* microdialysis has historically been performed in rats, but with the advent of genetically altered mice in the mid-1990s, manufacturers have miniaturized microdialysis probes to take advantage of these important models,

allowing neuroscientists to study the neurochemistry of knockout, knock-in and transgenic mice. Although the majority of microdialysis research has been preformed in rodents, the technique now is being employed in primates and humans.

Currently, there are over 100 compounds that have been identified as putative neurotransmitters in the mammalian brain, including small organic molecules (amino acids and monoamines), neuropeptides, and gaseous molecules (nitric oxide). Coupling microdialysis to analytical techniques with extremely low sensitivities is critical for detecting the nanomolar to picomolar levels of neurotransmitters present in discrete brain regions. Typically, microdialysis is coupled to separation techniques such as high performance liquid chromatography (HPLC) or capillary electrophoresis (CE) and electrochemical, fluorescence, or mass spectrometry to detect the neurotransmitter(s) of interest. Coupled to sensitive detection techniques, microdialysis is ideal for studying low levels of neurotransmitters as they function in the vast extracellular milieu.

As stated in the opening sentence, there are currently about 14,000 journal articles on the topic of microdialysis and an exhaustive review of the microdialysis literature is beyond the scope of this review chapter. However, we do invite the reader to use our list of references as a starting point if they are at all interested in this technique.

## 1 INTRODUCTION

### 1.1 Historical Perspective: Microdialysis

Earlier techniques before microdialysis included a "push–pull" method, first developed by Gaddum et al. in 1961. In this design, liquid enters the brain through one tube while another tube adjacent removes the fluid that entered the tissue at the same time [1,2]. The "push–pull" technique has several disadvantages; possible tissue damage from pressure due to a high flow rate, inefficient recovery of injected fluid, or the removal of tissue if the flow rates are not correctly balanced [1,2]. Bito et al. in 1966 first engineered enclosed dialysis membranes bags with a 6% dextran saline solution, which allowed analytes to be separated and collected within the tissue. The sac was placed in various tissues and allowed to equilibrate within the surrounding area [2,3]. After several days, the sac was then removed and the analytes of interest, mainly amino acids from the neck and brain tissue, were measured [2,3].

This first attempt using a dialysis membrane overcame some of the problems associated with the "push–pull" method by using the membrane bags, but a second surgery was required to remove the dialysis membrane to collect the sac containing the analytes [2,3]. In 1972, Delgado et al. developed a modification of the push–pull cannula technique termed a "dialytrode" which was able to provide continuous monitoring of analytes. The general construction of the dialytrode consists of two tubes that are connected to a dialysis membrane bag composed of polysulfone [1].

Ungerstedt and Pycock [4] later refined the dialytrode technique using several different designs. One design includes a dialysis membrane made of cellulosic tubing

with an outer diameter of approximately 250 μm and a molecular cutoff weight of less than 5 kDa [4]. The dialysis tubing is attached to steel tubes and bent into a loop to allow perfusion [4]. Using this innovative technique, Ungerstedt and Pycock examined the neurotransmitter dopamine (DA) following an injection of amphetamine in the brains of awake and freely moving rats [4]. The development of this novel microdialysis probe has provided great insight into the *in vivo* functions of a wide variety of neurotransmitters, and is still the technique of choice for understanding neurochemical transmission *in vivo* [4–9].

## 1.2 Basics Principles of Microdialysis

The semi-permeable membrane of the microdialysis probe has a typical molecular weight cut off between 5 and 30 kDa, which allows the probe to exclude macromolecules such as proteins and enzymes [2]. As shown in Fig. 1, the semi-permeable membrane permits the free diffusion of hydrophilic, low molecular weight

***FIGURE 1*** *Concentric microdialysis probe used for in vivo analysis of neurotransmitters. Small hydrophilic molecules are able to pass through the semipermeable membrane, while larger molecules such as proteins including enzymes are excluded.*

compounds. The probe can be implanted in almost any kind of tissue or organ including the brain, blood vessels, eyes, tumors, or the liver [10]. Syringe pumps are used to push a perfusate, usually a fluid mimicking the extracellular fluid of the tissue, into the inlet tubing of the probe at low flow rates; approximately 0.5–5.0 μL/min [10]. Once the perfusate reaches the semi-permeable membrane, dialysis sampling occurs based on the principle of diffusion. A concentration gradient exists between the perfusate, which typically is missing the analyte of interest (neurotransmitter) allowing for diffusion of the neurotransmitter from the sample matrix to the microdialysis probe. Mass transport of the analytes of interest flows down their concentration gradient, which in most cases is toward the probe. The analytes then diffuse through the semi-permeable membrane, to be carried away by the perfusate and into the dialysate sample [2,11,12]. Dialysis is defined as the exchange of analytes occurring at the membrane interface between the lumen and the tissue [12–14]. Analytes in the perfusate may also diffuse from the lumen of the probe into the sample matrix, a reverse process known as retrodialysis [13]. Typical microdialysis analytes include neurotransmitters such as biogenic monoamines, amino acids, and neuropeptides, metabolites such as glucose and hormones, and pharmaceutical or illicit drugs such as fluoxetine, methylphenidate, cocaine, or amphetamine [15]. After a fraction is collected, it is separated and coupled to the most appropriate analytical technique to determine and measure its components [16]. As shown in Fig. 1, microdialysis can be viewed as a crude separation technique that allows only hydrophilic, low molecular weight compounds to diffuse through the membrane. The power of microdialysis is that this technique can be coupled to the most appropriate analytical technique for the analytes of interest to be detected and measured [16].

## 1.3 Common Probe Characteristics and Basic Setup

Several kinds of probe designs exist, though all must have common features necessary to ensure successful dialysis. These features include a dialysis membrane that is hydrophilic and can consist of compounds such as polycarbonate, regenerated cellulose, or polyacrylonitrile (see Fig. 2) [10,14]. The dialysis membrane usually has an outer diameter of approximately 250–350 μm and a length between 1 and 10 mm [10,13]. The basic microdialysis setup is shown in Fig. 3. The animal is connected to a swivel by a collar that allows free movement within the cage. The swivel is attached to a balanced arm to prevent tubing from tangling or twisting. The syringe pump sits on top of the table and pumps the perfusate into the implanted microdialysis probe, which is situated inside a guide cannula which has been surgically implanted into the brain. The dialysate is pumped slowly through the membrane and out the other side, allowing time for analytes to diffuse into the fluid. The sample is then collected at regular intervals and analyzed for compounds of interest [1] [17].

[1] If the reader is interested a detail description for setting up the monoamine microdialysis measurements they are referred to the Acworth reference.

***FIGURE 2*** *Chemical structures of the different types of hydrophillic membranes used.*

***FIGURE 3*** *In vivo microdialysis setup. If setup were for online analysis the microdialysate sample would be directly connected to a HPLC, CE or microfluidic system. If off-line analysis was being used the outlet tubing would be inserted into a microcentrifuged tube.*

## 1.4 Advantages and Potential Pitfalls

Microdialysis as a sampling technique has four important advantages: (1) the construction of the probe allows for discrimination of molecules based on molecular weight, (2) the ability to continuously monitor analytes *in vivo* over a long period of time, (3) different probe designs allowing sampling flexibility for numerous types of tissue or organs, and (4) the ability to couple microdialysis to sensitive analytical techniques allows the detection and measurement of low nanomolar to picomolar concentrations of analytes (see Section 2) [2,12]. Since the microdialysis probe is small (diameter ~200 μm, length 1–4 mm), it does not severely damage the tissue (but see Section 1.7 for a complete discussion of tissue damage related to the microdialysis probe), and is capable of separating out discrete brain regions such as the caudate–putamen, nucleus accumbens, ventral tegmental area, hippocampus, and frontal cortex. In a few studies, multiple microdialysis probes have been implanted into different brain areas such as the caudate–putamen and ventral tegmental area of the same animal to examine different release profiles of neurotransmitters to the same exogenous drug [18,19]. Microdialysis as a sampling technique is both sensitive and discriminating. Though small analytes are allowed to diffuse into the probe, proteins and enzymes are excluded, which allows the collection of analytes without fear of degradation [2,12] The technique is used in pharmacokinetic studies to examine absorption of the drug of interest, effects of the drug on the system, metabolism, and elimination, and can be used for studies of novel therapeutics, hormones, steroids, or other compounds [12,20,21]. Samples collected can be analyzed immediately without further purification by several analytical techniques (see Section 2). Finally, because microdialysis employs continuous sampling, multiple measurements containing many analytes can be taken over an extended period of time, reducing the number of animals used [2].

Microdialysis is a very common, sensitive, and useful technique for *in vivo* sampling. However, as with any technique, there are pitfalls associated with its use. Although the dialysis membrane can sample low molecular weight compounds (~<7000 Da) and provides a fairly clean sample, but this semi-permeable membrane excludes hydrophobic molecules, analytes bound to proteins, or high molecular weight compounds [2,12]. Due to the limitations of the dialysis membrane, some classes of molecules have been overlooked, such as proteins and small peptides, which, though they are not "fast" neurotransmitters, play a critical role in neuromodulation [16,22–25]. Further, microdialysis sampling does not take place at equilibrium, with only a limited time for diffusion, and thus only a percentage of the analyte is actually recovered (see Section 1.6.1). Additionally, analyte recovery is dependent upon the path of diffusion through the extracellular fluid. Molecules must first come into the vicinity of the probe, and then overcome tortuosity, in which molecules do not take direct paths to the probe membrane, and must overcome barriers to diffusion [5,15]. The path to the microdialysis membrane is complex, involving potential interactions between receptors, transporters, and degrading enzymes of the analyte of interest [5,15]. As shown in Fig. 4, it is easier for the analyte to diffuse down its concentration gradient toward the membrane in *in vitro*

***FIGURE 4*** *The diffusion paths of analytes in an in vitro compared to an in vivo system. In in vitro studies, analytes have a direct path to microdialysis membrane. In in vivo, analytes do not have direct path but are forced to travel around cells, but they also may be taken up by cells or enzymatically degraded in the extracellular fluid.*

studies compared to *in vivo,* where the numbers of complex biological interactions is dramatically increased.

Another potential pitfall is the flow rate used. The perfusion flow rate can determine the amount of analyte recovered from the sample matrix. The slower the flow rate, the more time is allowed to approach equilibrium, and the higher the percent recovery of the analyte [12]. However, lowering the flow rate to sub-1 μL/min results in longer collection times, smaller sample volumes recovered, and poor temporal resolution [12].

Another point that has drawn considerable criticisms is the tissue damage associated with microdialysis after insertion of the probe [26–30]. Microdialysis was originally thought as a 'minimally invasive' technique, but recent studies have shown that the area around the probe and up to 1.5 μm away might be compromised; leading to decreased accuracy of analyte measurements (see Section 1.7) [26,28].

## 1.5 Probe Designs

There are several different probe designs available, though all contain dialysis membranes that are hydrophilic, and probes between 1 and 10 mm long with an outer diameter of approximately 250–350 μm [10,13]. Different probes have been developed over a number of years that are specific for various types of target tissue, a development that has increased the versatility of the microdialysis technique. The next few sections describe these different designs as well as their applicability.

***1.5.1 Side-By-Side and Loop Probe*** First introduced by Sandberg et al. in 1986, the side-by-side probe consists of two flexible tubes next to each other, with one slightly longer than the other (see Fig. 5). The longer tube is inserted into the dialysis membrane, while the shorter tube is positioned parallel to the long tube outside the

***FIGURE 5*** *Schematic of side by side and loop probe designs.*

membrane [5]. As the perfusate enters the longest tubing, it flows to the bottom of a round dialysis membrane and flows up through the shorter tube. The molecular cut-off weight of the dialysis membrane is approximately 3 kDa and the diameter of the probe is approximately 300 μm [5].

Loop probes can be made using a short piece of dialysis membrane tubing attached to two steel cannulae. There is approximately 12 mm of dialysis membrane exposed between the two cannulae, but the exposed membrane can be as large as 2–4 cm [11] The dialysis membrane is then folded into a tight loop to create the loop design. One end of the steel cannulae is connected to a pump to push the perfusate through the probe while the other end is the outlet. These membranes have an approximately cut-off weight of 5 kDa and are suitable for subcutaneous tissues or the peritoneal cavity (shown in Fig. 5) [7,11].

***1.5.2 Concentric Cannula Probe*** The concentric cannula probe was first developed by Zetterstrom et al. and later refined by Hernandez et al. and Ungerstedt [9,11]. The concentric cannula probe consists of a round dialysis membrane attached to a metal or non-metal cannula with two pieces of tubing. As shown in Fig. 1, one tubing (inner) is placed inside the other tubing (outer) to create a concentric design. [5,12,13]. The inner tube extends past the outer tube down to the tip of the dialysis membrane. As the perfusate solution travels down the inner tube, it flows to the end of the dialysis membrane and diffuses from the inner tube to the membrane. Concentric probes are approximately 250–350 μm in diameter and

varying length ranging anywhere from 1 to 4 mm in rodents to 6–10 mm in primates [13]. The major function of this type of probe is to measure neurotransmitters from the brains of either mice, rats, monkeys, or humans [11].

The concentric probe has an inflexible structure that makes it stable and sturdy enough to be implanted into the brain. First, a guide cannula containing a "dummy" filler is inserted into the brain, directly above the region of interest, and is fixed into place in the skull using glue or dental cement with bone screws [11]. After the guide cannula surgery, the animals are given a post-operational recovery varying from a few hours to a few days. After recovery, the "dummy" is removed and the microdialysis probe is inserted in its place [11,12]. An advantage of the concentric microdialysis probe is that analytes can be measured *in vivo* in freely moving awake animals without major damage to brain tissue. Though the majority of research with concentric probes has measured neurotransmitters within the brain, the concentric probe has also been used to measure drugs in the eye cavity of rabbits [13]. Although the concentric probe design is convenient for sampling in the brain, it is not intended for use in blood vessels or internal organs because of its inflexible design, and the high probability that tearing or piercing of the tissue or vessel may occur [12,13].

***1.5.3 Flexible Probe*** Developed by Wages et al. in 1986, and further refined by Telting-Diaz et al. in 1992, the flexible probe is designed to overcome the inflexible nature of the concentric probe [31,32]. The flexible probe is composed of two pieces of fused silica tubing having internal diameters of 75 μm placed in 5-mm long polyethylene tubing. For a side-by-side design, one of the tubing pieces is introduced into a polyethylene tube and extended out approximately 5 mm, while the other fused silica tubing is inserted into the polyethylene, but does not extend beyond the tubing [32]. The dialysis membrane is placed on the fused silica tubing extending beyond the polyethylene tubing and the end is sealed with epoxy (shown in Fig. 6) [32]. Because the flexible probe eliminates the structural support of the

***FIGURE 6*** *Flexible probe, which has a similar design to concentric probe, but has flexible tubing for intravenous use.*

***FIGURE 7*** *Modification of a flexible probe that has catheter design.*

cannula design, damage due to tearing or piercing of tissues or vessels is reduced and allows for this style probe to be used intravenously, most commonly in the jugular vein [11–13]. Although the flexible probe overcomes the structural disadvantages of a concentric cannula probe, it is difficult to attach the probe to target organs such as the liver or muscle without disrupting the integrity of the tissue. Yang et al. reported on a flexible concentric probe using a catheter design for insertion into the inferior vena cava of rats (see Fig. 7) [11,33]. This new type of design allows for easy placement in the vessel and prevents the membrane from being easily damaged since it is placed in the middle and not at the end [11].

***1.5.4 Linear Probe*** The linear probe, designed in 1974 by Ungerstedt and Pycock, is a flexible design suitable for implantation in peripheral tissues or organs such as the liver, muscle, and skin (dermis), as well as sampling from tumors and fluid from the spine [11–13]. The probe is made by taking a hollow fiber membrane and attaching it to flexible tubing (Fig. 8). A skeleton fiber is then inserted into the flexible tubing and dialysis membrane to provide support, as well as to assist with implantation of the probe by threading it through the desired tissue [13,34]. The skeleton fiber also protects the membrane from being damaged. After the inlet and outlet ends of the flexible tubing are glued in place, the skeleton fiber can be removed if necessary. There are several advantages to using the flexible probe, including making direct contact with the sample of interest, reducing tissue damage due to probe flexibility, and increased structural stability allowing the probe to be used

***FIGURE 8*** *Linear probe design. Completely flexible and is used in peripheral tissues such as the muscle and dermis.*

***FIGURE 9*** *Shunt probe design used in the liver to analyze bile.*

*in vivo* [13,34]. Linear probes are most often used to examine the effects of drugs in tumor tissue and in the extracellular fluid of skin tissue, studying red blood cell binding, and for kinetic studies involving enzymes *in vitro* [13]. Unlike the concentric probe, the flexible probe is unable to be used in the brain because of its large size, making it difficult to distinguish between specific brain regions [13,34].

***1.5.5 Shunt Probe*** The first shunt probe was designed in 1993 by Scott and Lunte, to examine the contents of the liver (Fig. 9) [35]. The design of the shunt probe consists of a membrane approximately 3–6 cm long (attached to flexible tubing), which is inserted into a piece of polyethylene tubing [11] The inlet of the polyethylene tubing is inserted and secured with sutures into the bile duct toward the liver and the outlet is inserted into the small intestine. The sample can then flow past the dialysis membrane and interact with the perfusate that is pumped in the opposite direction through the flexible tubing [11–13,36,37]. The advantage of the shunt probe design is that it allows for continuous sampling of the bile (generally low molecular weight compounds) from the liver [35]. Previous designs have collected bile over an extensive period of time (>48 h), which can lead to the break down of bile or alter the effects of drugs. The shunt probe offers a major advantage in that samples from bile can be tested continuously without degradation over long periods of time [35]. Therefore, several experiments testing the metabolism of bile or drug studies involving the analyte of interest can be determined in rats [35]. Additionally, the shunt probe has been used for desalinating samples for analysis in mass spectrometry (MS). However, the shunt probe must flow continuously, while the flow of bile is sometimes sporadic, due to influences of body temperature, bile concentration, and anesthesia or drugs administered into the system [37].

While there are currently several types of probes in use and more in development for sampling of tissues, it remains clear that the principles and measurements obtained

from microdialysis remain the same. We shall now shift to discussion of the technical points of microdialysis, which apply across probe types.

## 1.6 Calibration

One of the critiques of microdialysis is that concentration of neurotransmitters, when uncorrected for probe recovery, vastly underestimates actual extracellular concentrations in the brain [26,38]. The extracellular value typically reported in microdialysis experiments does not correct for *in vivo* recovery [26,38]. Several mathematical theories of mass transport in microdialysis experiments have evolved over the past 30 years which have led to methods to correct for *in vivo* recovery [5,39,40]. One issue that should be considered when determining quantitative determination of extracellular neurotransmitter levels is the recovery of the dialysis probe. Recovery of neurotransmitters from the brain by microdialysis is low (<50 %) and varies between individual probes and animals [38] However, the microdialysis probe is unable to recovery a 100% of the analyte from the brain matrix due to barriers arising from probe material, length, and area of the membrane, diffusion coefficient, flow rate, matrix tortuosity, and temperature. Firstly, we will discuss calibration of microdialysis probes *in vitro*, and then discuss three methods for estimating basal extracellular levels *in vivo* that have evolved to correct for probe recovery: zero flow, zero net flux, and retrodialysis.

The barriers to probe recover can be compensated for in a variety of ways. For example, it has been shown that if the material of the dialysis membrane is composed of polyacrylnitrile (PAN), which is a thicker (30 μm), more negatively charged membrane compared to polycarbonate or regenerated cellulose membranes (9 μm), anionic compounds will have a lower recovery with PAN membranes versus other membranes compared [11]. Increased length of the microdialysis membrane will increase percent recovery because a larger surface area is available to sample from the matrix, though the length of membrane used depends heavily on the tissues being sampled [2,10]. In brain tissues, shorter membranes (<2 mm) are typically used, while longer membranes are used in other tissues such as the muscle, allowing for increased recovery of analytes compared to brain [11]. The diffusion coefficient of the analyte is also affecting probe recovery. The diffusion coefficient is defined by the amount of analyte that travels through a concentration gradient over a certain area and time [11]. Based on the equation by the Stokes–Einstein relation, the diffusion coefficient is directly related to the viscosity, temperature, and the size of the analyte. Therefore, higher molecular weight compounds (or molecules with a larger radius) have a lower diffusion coefficient than lower molecular weight compounds and will hinder probe recovery. Finally, to optimize probe recovery, the temperature must be consistent with the sample matrix. For this reason, the perfusion liquid is generally kept at 37°C, or equalized to the temperature of the *in vitro* tissue being sampled [2].

As can be seen from above, probe recovery is dependent on a number or factors, many of which the experimenter can manipulate to optimize *in vivo* recovery. To further increase the amount of analyte recovered from the sample matrix, other factors must be taken into additional consideration. Flow rate of the perfusate can be

decreased, which increases in the amount of analyte recovered, by increasing the amount of time available for diffusion [12]. However, decreasing the flow rate also results in poor temporal resolution (how precise measurements are over a period of time) due to longer collection times and smaller sample volumes [12]. Additionally, the concentration of the analyte in the dialysate sample can be increased by adding inhibitors that prevent degradation or uptake [2]. For example, using a selective serotonin reuptake inhibitor will increase the amount of extracellular serotonin and increases the concentration in the sample matrix [41].

***1.6.1 In Vitro Microdialysis Calibration*** In the past, one of the most common methods for evaluating the recovery of the microdialysis probe was to perform *in vitro* recovery, which was used as an index of *in vivo* probe recovery [11]. *In vitro* recovery of the probe is a fairly straightforward process. The probe is placed inside a beaker (typically well stirred and at 37°C, although room temperature has been used) containing a known concentration of the analyte of interest in extracellular fluid. The inlet side of the microdialysis probe is perfused with extracellular fluid, and the sample is collected and measured by an analytical method (see Section 2). The *in vitro* relative recovery ($R$) of an analyte is defined by the following equation:

$$R = C_{\mathrm{p,f}}/C_{\mathrm{e,f}}$$

where $C_{\mathrm{p,f}}$ is the concentration of the analyte obtained from the microdialysis probe and $C_{\mathrm{e,f}}$ is the concentration of analyte in the beaker. Although *in vitro* recovery used to be a popular technique to estimate *in vivo* recovery, it is not considered as reliable as more recent *in vivo* methods. An *in vitro* solution is not a complex matrix where active biological processes are taking place, and where the path length of analytes to the microdialysis probe is tortuous, limiting the mass transport of the analyte. Instead, *in vitro* recovery allows for diffusion without all these complicating factors, which can drastically alter the recovery of a probe *in vivo*. Thus, the *in vitro* model is not capable of mimicking the *in vivo* system accurately, and in recent years has given way to the recent *in vivo* methods of zero flow, zero net flux, and retrodialysis.

***1.6.2 Flow Rate Method: Extrapolation to Zero Flow and Zero Flow Rate*** The zero flow method is based on the principle that recovery of the probe is inversely proportional to the flow rate, meaning the slower the flow rate, the greater the recovery [11]. Typical flow rates for rodent microdialysis experiments are in the order of 1–2 μL/min, allowing a collection of 10–20 μL in a 20 min sample. These flow rates permit a respectable sample size for analysis, while staying within a biologically relevant timescale. Because recovery is inversely proportional to flow rate, the flow rate and the relatively recovery can be used to extrapolate to the point of zero flow. In zero flow microdialysis, various flow rates ranging from 0.3 to 5 μL/min are chosen and the analyte's concentration is determined at each flow as a function of the flow rate. The data are fitted and one can extrapolate (estimate the value) to a steady state, defined as the point when the probe is in equilibrium with the extracellular fluid.

Justice and co-workers took this analysis one step further by deducing that, if one measured the concentration of analytes at very slow flow rates (<100 nL/min), the dialysate and extracellular space would be near equilibrium [42]. At very slow flow rates, the dialysate has the maximum time to equilibrate with the extracellular space, allowing for the greatest possible recovery. The advantage of this slow flow technique over the extrapolation method is that only one flow rate is evaluated, a less time consuming design than changing flow rates and waiting for equilibrium to be re-established for each measurement. The drawback with both methods, however, is poor temporal resolution, as flow rates less than 1 μL/min involves longer sampling times to obtain the needed quantity of sample. Additionally, the method of slow perfusion rate may be hindered with sample evaporation during long collection times as well as the stability of the slow perfusion rate [42]. This means either (a) longer collection time is necessary to obtain a sample, or (b) a microbore or CE system will be required coupled with a normal sample time and low flow rate, to analyze a small sample volume adequately.

***1.6.3 Zero Net Flux*** Zero net flux is a method that is commonly used to estimate basal neurotransmitter levels *in vivo*. In zero net flux experiments, the concentration of the analyte of interest is perfused into the brain region of interest at various concentrations ($C_{in}$; concentration of the analyte going in). Diffusion will then take place *in vivo* across the dialysis membrane. The amount of analyte exiting the microdialysis probe is defined as $C_{out}$. When $C_{out}$ is greater than the amount of analyte being perfused, there is a net gain of the analyte in the microdialysis probe as neurotransmitter diffuses into the sample (represented by the positive $y$-axis values; see Fig. 10). However, if $C_{out}$ is less than the amount of analyte being perfused, there is less extant neurotransmitter in the brain than in the perfusate. Thus, there is a net loss of analyte in the sample as it diffuses from the microdialysis probe to the brain. Determination of zero net flux is plotted as a linear regression plot, where $C_{in}$ is plotted on the $x$-axis and the difference between $C_{in}$ and $C_{out}$ appears on the $y$-axis. The point where the line crosses the $x$-axis is referred to as $C_{ext}$, where the Concentration perfused in is the same as that in brain, resulting in no diffusion across the membrane (the point of zero net flux). This point represents an estimate of the concentration of the extracellular neurotransmitter of interest that corrects for sub-maximal recovery across the dialysis membrane. Previous studies by Justice and co-workers have shown that changes in transporter function can alter microdialysis probe recovery [43–47]. Thus, it has been hypothesized that the only biologically significant process affecting probe recovery is the active uptake of neurotransmitters by their plasma membrane transporters.

***1.6.4 Retrodialysis*** An advantage of using the microdialysis technique is that it allows for the perfusion of an exogenous drug (antagonist or agonist) or analyte directly into the target tissue to measure the local response. Retrodialysis takes advantage of this ability by applying an internal standard to the perfusate. Retrodialysis is based on the principle that the relative loss (RL) of the internal

***FIGURE 10*** *A hypothetical graph of no net flux. The x-axis represents the amount of neurotransmitter being perfused into the brain ($C_{in}$), while the y-axis represents the difference between the amount of neurotransmitter being perfused in and the amount that is measured ($C_{out}$). Where the line crosses the x-axis ($y = 0$) is the point of no net flux and represents the corrected neurotransmitter level.*

standard is related to the relative recovery (RR) of the analyte of interest. Relative recovery as defined in *in vitro* experiments is the concentration of the dialysate ($C_d$) divided by the concentration of the extracellular levels ($C_{ext}$), while relative recovery is defined as the loss of the internal standard to the tissue ($C_{perfusate} - C_{dialysate}$) (divided by the concentration in the perfusate. Using retrodialysis as a calibration model entails perfusion of a non-native neurotransmitter with a similar chemical structure, for example *N*-methyl-serotonin for the neurotransmitter serotonin [48]. However, the relative recovery being measured is not from the analyte of interest, but rather the recovery of the non-native neurotransmitter. The recovery of the non-native neurotransmitter is used to make assumptions about the recovery and diffusion of the native neurotransmitter, assuming the non-native neurotransmitter has values equivalent to the analyte of interest [49]. Retrodialysis overcomes some of the disadvantages associated with *in vitro* probe recovery by placing the probe in the complex biological matrix. However, the non-native neurotransmitter used may display different properties compared to a native neurotransmitter with respect to metabolism and uptake *in vivo* and these issues are often overlooked. Although this method appears to have more advantages compared to *in vitro* microdialysis, it is still not a widely used method for calculating *in vivo* recovery.

## 1.7 Tissue Damage

One of the major hurdles associated with *in vivo* monitoring is the tissue damage which occurs when inserting a probe into the brain [50]. Although, relatively speaking, the microdialysis rodent probe is small ($\sim$200 μm in diameter, length of

1–4 mm), and the damage is often described as minimally invasive [16,50], local tissue responses must be taken into consideration. Following surgical implantation of the probe, a series of responses develop near the implantation site. Firstly, within 2 days of implantation, edema and leukocytes surround the probe. There may also be hemorrhaging and accumulation of polymorphonuclear leukocytes (a type of white blood cell signifying an immune response). Macrophages (another characteristic response to foreign invasion) are also observed in the implantation area between 2 and 3 days following surgery [13]. Ungerstedt et al. has observed an increase in g (28) lucose metabolism, decrease in blood flow, and a decrease in transmitter release taking place after probe insertion, which could last from minutes to hours depending on the type of tissue being analyzed [2]. Beneviste demonstrated similar effects, showing an increase in glucose metabolism with decreased blood flow after approximately 3 h, but recovering after 24 h [5]. Beneviste also observed astrocyte growth 3 days after implantation, and after 14 days, reticulin-positive fibers were present and had encapsulated the probe [5]. Previous studies have also shown edema, hemorrhages, monocytes, and an increase in the number of vacuoles (vacuolization) present in the probe implantation area [5].

Clapp-Lilly et al. have also studied the effects of dialysis probe tissue damage, measuring intracellular disruption and damage in rat striatal tissue. Following implantation of a microdialysis probe, there was evidence of decreased neuronal density in the striatum ~400 um away from the probe tract, and intracellular disruption as far as 1.4 mm away from the probe [28]. The group then performed a more extensive study of tissue damage, finding evidence of neuronal damage, compromised synapses, and disruptions in neurotransmitter release up to 1.4 mm away from the probe [28]. Using light microscopy, they observed neuronal damage, including myelinated axon damage, at 0–100 um distance from the probe site. At 350 μm, axons containing fiber bundles were swollen, and at 500 μm there was general visible neuronal damage [28]. Between 500 and 1000 μm from the probe site, some neurons appeared normal, while others showed evidence of degeneration with the presence of vacuoles. Astrocytes present within this range also showed signs of swelling [28]. With the use of electron microscopy, Clapp-Lilly et al. further observed the effects of probe implantation on gliosis (the accumulation of large numbers of astrocytes, occurring at sites of tissue damage or injury) at distances of 0–300 μm [28]. At 300–400 μm, neuron damage was less severe, though there remained evidence of gliosis and darken neurons. Even at the distance of 1.2–1.4 mm, there was still observation of deteriorating mitochondria within neurons, synapse damage, and damage to myelinated axons [28]. Given these observations, it is clear that substantial tissue damage takes place following microdialysis probe implantation in to the brain tissue.

Given the evidence of tissue damage at some distance from the site of probe implantation, there has been some debate over the effectiveness of microdialysis measures. If synapses and neurons are severely damages, how can microdialysis correctly estimate the concentration of biological molecules in the area of interest [27,30]? In a study to assay the effects of microdialysis probe implantation, Bungay et al. examined the function of the neurotransmitter dopamine. Two common

techniques, microdialysis and voltammetry, were observed for the effects of tissue damage [27]. After observing the clearance rates of dopamine from the extracellular fluid of brain tissue, Bungay et al. found that uptake rates for dopamine were higher when measured via voltammetry. This suggests that tissue damage may be less using voltammetry techniques, possibly due to the smaller size of the voltammetry electrode [27]. The authors concluded that microdialysis was not an accurate depiction of extracellular dopamine or dopamine clearance rates, presumably due to the extensive amount of tissue damage following probe implantation [27]. In an unrelated study, Grabb et al. examined the effects of acute (3 h) versus chronic (24 h) implantation of probes in the brain [51]. Both acutely and chronically implanted probes showed no difference in the amount of microvascular hemorrhaging [51]. Though at the 24 h time point there were significant increases in inflammation, fibrin (a blood clotting factor), edema, and the presence of microglia. Probes implanted for only 3 h showed no increase in the number of microglia present compared to controls, and though macrophages where present, there were low levels compared to the 24 h times point [51]. Finally, chronic probe implantation showed no difference in the amount of astrocytes present, while increased astrocytes were seen in the acute probe implantation. Results by Grabb et al. thus suggest that chronically implanted probes may be less accurate in ascertaining extracellular analytes levels, due to increases in inflammation, edema, and fibrin, and that new probe designs or implantation methods should be developed to overcome these issues [51].

## 2 ANALYTICAL METHODS

### 2.1 Introduction

Microdialysis itself is not a sensitive technique, but coupling microdialysis to a wide range of separation methods and sensitive detectors can improve its versatility and power. Although it is possible to couple microdialysis to techniques without a separation step such as immunoassays or mass spectrometric analysis, the majority of microdialysis studies employ a separation component, such as liquid chromatography or capillary electrophoresis (CE), to separate small molecular weight analytes from one another [52,53]. Once the analytes are separated, a sensitive detector is required to measure the low concentrations of endogenous compounds. A variety of analytical instruments are used to detect the analytes of interest, including ultraviolet-visible (UV–Vis) detector, electrochemical detection, fluorescence, and mass spectrometry.

### 2.2 Online vs. Off-Line Collection

After the analytes of interest in the extracellular space perfuse down their concentration gradients and into the probe, the samples can be collected in one of two ways; “online” or “off-line”. Both online and off-line systems have essentially the same setup; a syringe pump, a syringe selector if more than one perfusion liquid is required,

and a microfraction collector to collect the sample (off-line). For online collection, the microdialysis tubing feeds directly into the injection valve for automated collection, taking the place of the microfraction collector. When using the off-line collection method, samples are collected into microcentrifuge tubes and placed on ice during collection or immediately frozen after collection has finished [45,54]. The advantage of the off-line method is that many animals can be dialyzed at the same time, without being limited by the number of analytical instruments available. Samples are collected manually by changing vials or automatically using a fraction collector [2]. Fraction collectors automate off-line collection, which minimizes the handling of small sample volumes, providing an easy interface to collect from multiple (2 or 3) probes. Samples collected off-line are stored at −80°C and analyzed at a later time point [55]. It is important to ensure that the microcentrifuge tubes are immediately sealed and stored properly to prevent evaporation of the sample [2]. Some fraction collectors have a sophisticated system that keeps the microcentrifuge tubes refrigerated and sealed. Temporal resolution for off-line collection is governed by the dialysate flow rate and the amount of sample required for analysis [10]. If the analyte of interest is below the detector's limit of detection, then dialysate samples must be collected over a longer period of time, which results in poor temporal resolution [56].

The online collection method is used when the outlet tube of the probe is connected directly to a sample loop with a valve. The sample can then be directly injected into a high performance liquid chromatography (HPLC) or CE system. There are several advantages to using the online method: (1) samples can be analyzed in real time without evaporation [2,20,56], (2) automated sample collecting is easier for sub- to microliter sample size, (3) longer experiments can be performed without the presence of the experimenter (>12 h), and (4) near real-time monitoring of the resulting chromatograms can be performed. Real-time monitoring allows the experimenter to immediately identify problems with the experimental subject, microdialysis probe, flow, or co-eluting peaks, and thus to trouble-shoot them before the experiment can be compromised. When using the online collection method, both the microdialysis and the chromatogram systems have to be optimized simultaneously [2]. In online microdialysis, the temporal resolution is dependent on the run time of the chromatography (or other analysis system). For example, if it takes 30 min to resolve the analytes, then the next dialysate sample cannot be injected, separated, and analyzed until the end of the previous sample. Furthermore, the sample must be flushed properly during online collection, or there will be carry-over into the next collection. Samples can also be lost to waste if there is a time separation between injections. Despite this, online collection is useful for long, optimized experiments with small sample sizes [13].

## 2.3 Separation Techniques (Chromatography)

Microdialysis is itself a separation technique, capable of discriminating sample molecules by molecular weight, but chromatography is often utilized to further separate structurally similar molecules collected by dialysis from one another.

***FIGURE 11*** *Schematic of HPLC setup with major components which include the HPLC pumps (gradient example shown), degasser, injector, guard column, column, and detector.*

Although there are many types of chromatography including size-exclusion, ion exchange, and affinity chromatography, the chromatography techniques generally used for microdialysis include HPLC or CE [57]. Separation techniques like HPLC and CE are popular for several reasons: (1) ability to analyze a wide variety of biological materials including blood, tissue, urine, and cerebral spinal fluid, (2) ability to accommodate small sample volumes, and (3) reasonable temporal resolution of analytes of interest [13,57,58].

***2.3.1 High Performance Liquid Chromatography*** The objective of HPLC is to separate chemically related species present in a single mixture [57]. In HPLC, the sample is transported via a liquid mobile phase, and forced through a solid stationary phase packed into a rigid column [57]. As shown in Fig. 11, the HPLC instrumentation setup contains the following components: a degasser, HPLC pump, guard, and analytical column, and detector. The degasser is used to remove any bubbles that may occur due to oxygen and nitrogen present in the mobile phase. The bubbles are removed by purging the system with helium gas [59]. The mobile phase must run through the degasser prior to pumping through the HPLC system. If air is present within the system, these air bubbles could result in significant noise and loss of efficiency [59].

Depending on the analytes of interest, an isocratic mobile phase may be used, but in those cases where more than one mobile phase is required, gradient mobile phases are needed. Gradient mobile phases are produced by using more than one pump to mix different solvents with differing polarities, ionic strength, and concentration together [57,60]. Gradient elutions can be fashioned in a stepwise or continuous gradient, and are used to separate the sample more efficiently due to the difficulty of separating analytes with similar chemical characteristics [57,60]. The HPLC pump pushes the mobile phase and sample through the column at high pressures ($\leq$6,000 psi) [57].

Although there are several different HPLC pumps available, the most common is the reciprocating pump, which contains dual pump heads to push the solvent through. This ensures a constant flow of mobile phase through the system.

The column comprises the stationary phase of the system, over which the mobile phase containing the sample is run. The analytes can then separate based on the length of interaction with the stationary phase [60]. The time it takes for an analyte to elute from the column is known as the compound's retention time (RT). Columns used for microdialysis typically have an internal diameter of <5 mm containing packing particles between 3 and 10 μm, though particles as small as <2.2 um have recently been developed [57,60]. Since most biological molecules are polar, reverse phase liquid chromatography (RPLC) is used. A RPLC stationary phase column contains silica that has been modified with non-polar materials such as $CH_3$, $C_4H_9$, $C_{18}H_{37}$, or $C_8H_{17}$. The mobile phase for RPLC consists of polar solvents such as water with lesser amounts of acetonitrile or methanol [60]. Therefore, the more an analyte is retained within the stationary phase, the longer it takes for the analyte to elute or leave the column [60]. For example, the neurotransmitter dopamine is not only a small polar compound but also contains a non-polar aromatic ring moiety. This duality of structure allows this chemical species to interact with both the stationary phase of the column ($C_{18}$, non-polar) and the polar mobile phase. Molecules spending more time in the mobile phase versus the stationary phase have shorter retention times, while molecules interacting more closely with the stationary phase elute from the column later. The column stationary phase is normally stable, but it should be noted that extremes in pH can decrease the stability of the silica material and decrease the lifetime of the column. It is therefore recommended that the mobile phase pH is between 2 and 8.

To extend the lifetime of an HPLC and reduce maintenance time, guard columns and in-line filters can be used. Researchers use a guard column, which is placed before the analytical column to protect it from impurities and analytes that may bind irreversibly to the stationary phase. The guard column contains the same stationary phase as the column, with an increased particle size to account for the pressure difference between the two columns. Some analytical detectors are very sensitive, and the manufacturers may recommend an in-line filter to protect the detector from contaminants, not only from the mobile phase but also from the sample injected. This is especially true of microdialysis, as the dialysis membrane will allow very small peptides (<6,000 Daltons) to collect in the same. These peptides can be retained very easily within detectors or on columns, reducing column lifetime. Therefore, the use of guard columns or filters can prevent these materials from adhering to critical components of the system.

Ultimately, when analyzing low volumes and concentrations (low nanomolar) of monoamine neurotransmitters, amino acids, and other compounds, it is imperative that the HPLC system be optimized. One of the first concerns with separation techniques such as HPLC is that injection of the samples onto the column further dilutes a low volume and low concentration sample when it is combined with the mobile phase. This issue can be resolved by using a shorter column. There are several other factors that can affect the resolution, selectivity, and sensitivity of the sample

analysis [60]. First, the amount of dead volume within the HPLC system should be minimized to decrease the width of the peak (or band). The peak width is dependent on extra-column effects such as the volume required for the detector, length of tubing and connectors, or filters [58]. Column lengths and diameters should also be evaluated to determine if the correct size column is being used to elute the analytes of interest. A simple change to improve the sensitivity of the HPLC system is to decrease the column diameter (example from 4.6 to 3.0 mm). The smaller internal diameter of the column decreases the column volume dilution factor and band broadening for the analytes of interest, resulting in taller and sharper peaks. Failure to maximize the column efficiency results in band broadening and decreased resolution, which ultimately affects the quality of the sample being analyzed. Therefore, all steps to improve resolution, column efficiency, selectivity, and sensitivity should be careful considered.

***2.3.2 Microbore Liquid Chromatography (Microbore-LC)*** Types of liquid chromatography are often classified according to the column which is used. Use of columns with internal diameters less than 75 μm is referred to as nano-chromatography. An internal diameter from 25 to 100 μm is usually defined as capillary liquid chromatography (cLC), while 0.5–1 mm columns are classified as microbore. Microbore columns have been shown to have a 20-fold smaller cross-section compared to conventional columns (4.6 mm i.d.), which can lead to enhancement in sample concentration and decrease in band broadening [11,13]. Finally, narrow bore chromatography columns have internal diameters of 1–2 mm, and the conventional column width for microdialysis is around 4.6 mm. The internal particle size can also be changed to increase sensitivity. Ultra-performance liquid chromatography involves particles below 2 μm and results in detection at picomolar concentration, though retention time is sacrificed.

Traditional HPLC columns with an internal diameter of 3.0–4.6 mm are the most commonly used in *in vivo* microdialysis, though microbore columns, with their increased sensitivity to analytes, have recently enjoyed increased popularity. One report showed a 2000% increase in sensitivity using a microbore column compared to a traditional HPLC column [58]. Microbore columns also allow for the use of smaller sample sizes (1–10 μL), and can reduce the limits of detection. Finally, Justice and co-workers demonstrated that by using a microbore system, dialysate sampling time can be reduced to 1 min for the neurotransmitter dopamine, providing high temporal resolution for microdialysis [61].

Generally, conventional columns are used in microdialysis studies compared to microbore-LC or capillary-LC. Conventional columns do not generally require special instruments such as reduced flow rate pumps, low dead volume injectors, or a low volume detector, products that are often required on other systems. Also, extracolumn effects are not as much of an issue in a conventional system [58]. There have been many advances in column technology to optimize resolution, band broadening, selectivity, and sensitivity when using traditional columns. These areas are particularly important to microdialysis where small sample volumes with low concentrations of analytes are common.

***2.3.3 Capillary Liquid Chromatography (cLC)*** An emerging method to analyze microdialysis samples is cLC, which uses columns with internal diameters of 25–100 μm, compared to traditional columns with 3–5 mm internal diameters [13]. This decrease in internal diameter enhances the mass sensitivity to allow detection of attomolar analyte concentrations, a major advantage for microdialysis. In addition, small diameter columns lead to a reduction in flow rate, allowing this method of chromatography to be coupled very easily to mass spectrometer detectors [50,62]. Coupling with mass spectrometer detectors can prove useful in the measurement of compounds extant in the brain in picomolar concentrations. Recently, a number of microdialysis reports have coupled capillary liquid chromatography and mass spectrometry together for the analysis of neuropeptides [50]. cLC has several advantages over traditional microdialysis columns: (1) low band broadening (dispersion), (2) increased sensitivity to attomolar detection limits, (3) reduced mobile phase consumption, and (4) separation of up to 16 different amino acids from a sample volume of 200 nL [50]. However, the cLC method has several drawbacks. The system itself is unstable due to high sensitivity and the small size of the column diameter. The smaller internal diameter can result in frequent clogs and column exchanges. Analysis times are generally much longer than that of conventional columns. Finally, due to the sensitivity of the system, extracolumn effects are common and difficult to minimize [13,50]. Despite these drawbacks, cLC is a valuable tool for detection of rare compounds and small sample sizes.

***2.3.4 Capillary Electrophoresis*** Within the last 10 years, CE has grown in popularity in the microdialysis field, in part due to work from the Kennedy and Lunte laboratories [50]. CE can be performed with several different modifications, depending on the analytes of interest and the sensitivity required. These include capillary zone electrophoresis, capillary gel electrophoresis (gel matrix), capillary isoelectric focusing (separates amphiprotic species), capillary isotachophoresis (analytes migrate at the same velocity), and micellar electrokinetic chromatography (separate neutral or chiral species) [57,60].

CE is a separation technique wherein analytes are separated in open fused silica capillary tubing having an internal diameter of approximately 25–75 μm, as opposed to the column use required by chromatography [63]. The capillary is filled with a running buffer composed of an aqueous buffer solution [57,60]. Two electrodes, a positive and a negative (termed anode and cathode, respectively) are placed on either end of the setup (in the buffer reservoirs) and a voltage power is applied (shown in Fig. 12). An electric current is then generated which allows ions to migrate from the anode toward the cathode [57,60]. Therefore, the analytes of interest separate based on their charge (or electrophoretic mobility) and mass. The electrophoretic mobility of the analytes can be affected by the charge of the ion, viscosity or other frictional forces, the size of the ion, and its shape [60]. Highly positive ions will migrate faster toward the cathode compared to negatively charged ions, while larger ions will move more slowly due to their mass.

Samples are injected through hydrostatic forces such as gravity, pressure, or a vacuum. These methods can be achieved by raising the sample above the destination

***FIGURE 12*** *Schematic of CE set up. Capillary is exposed (gray box) to provide a detection window for UV–Vis or fluorescent detection.*

vial, applying pressure, or applying a vacuum at the destination end of the setup. Samples can also be introduced by electromigration, where the sample vial replaces the buffer reservoir and a voltage is applied for a period of time [57,60]. Electromigration is the preferred injection method, as it is the most efficient for drawing the sample into the fused silica for separation.

Capillary electrophoresis is advantageous in that band broadening and interferences are minimal. Flow velocity remains constant through the capillary, regardless of the position of the analyte in the tubing. This creates a "plug-like" flow and produces narrow bands [64]. The most important features of CE include rapid separation of

***FIGURE 13*** *The coupling of microdialysis to a microfluidic device. The probe can be placed in a vial for in vitro* or an animal for *in vivo* collection.

analytes, the option of small sample volumes (<10 nL), high mass sensitivity, high resolution, and low cost [16,63,65,66]. An additional feature of using CE is the ability to couple it to the wide variety of detectors that are commercially available as well as custom built detectors. CE can be coupled to laser-induced fluorescence, mass spectrometry, ultraviolet (UV) absorbance, and electrochemistry. The detector coupled to CE will vary depending on the analyte of interest [57]. By far the biggest advantage of coupling CE with microdialysis is the enhancement in temporal resolution. Samples can be collected and analyzed in 10-s intervals (>3000 samples for an hour of collection). For example, Qain et al. was able to determine a detection limit of 5 nM with a 1-min temporal resolution using CE coupled to electrochemistry [13]. CE also has the advantage of a low sample volume requirement (approximately 10–20 nL) Separation usually occurs after 70 s with a limit of detection of 100 nM [67]. CE has been used to identify and measure a wide variety of neurotransmitters, including amino acids, dopamine, substance P, serotonin, and noradrenaline as well as peptides such as luteinizing hormone-releasing hormone [16,63,66,68].

For off-line analysis using CE, sample volumes of approximately 1–7 μL are necessary. This avoids problems associated with the handling of sub-microliter volumes, evaporation, and loss in separation efficiency [13,50]. Initial attempts using off-line analysis involved collecting the sample in a vial, adding a derivatization agent if necessary, and injecting the sample onto the capillary. However, recent modifications of off-line collection have improved temporal resolution to 1–30 s. These modifications include mixing derivatization agents with the dialysate sample online prior to collection by using polyethylene tubing chambers, a method called "crossing" [50]. The outlet of the microdialysis probe is directly coupled to capillary tubing containing all of the necessary reagents for derivatization. After derivatization, a collection tube sends the derivatized samples to the vial. Therefore, sample collection, derivatization, and the actual separation are all online with no manual handling of samples. Lunte and co-workers was the first group to use NDA/CN to measure glutamate and aspartate online in the hippocampus of awake and freely moving animals [67]. In this CE method, two crosses were used. One cross was used to mix the derivatization agents, and the other cross to mix the derivatization agents with the dialysate sample [67]. The mixed sample is injected by a microinjection valve onto the CE [67].

Separations of 3–100 s are possible using capillary tubing of approximately 10 μm (length or diameter) [50]. However, there are several factors that can effect CE efficiency: injection length (including the volume of sample), diffusion of the analyte, electromigration dispersion (conductivity differences), joule heating, and solute interactions with the capillary wall [60].

***2.3.5 Microfluidics*** Within the last few years the area of micro-total analysis (μ-TAS) systems, or "lab-on-a-chip" devices has become a rapidly developing field, where sample introduction, separation, and detection occurs within a miniaturized or microfluidic analysis system [69,70]. These devices are engineered from various polymers or glass coated with a substrate of interest (Fig. 13). However, polymer chips

such as those made of poly(dimethylsiloxane) (PDMS) are more popular, being easy to make and less expensive compared to glass chips [69,70]. Microfluidic channels are approximately 10–100 micrometers in diameter or length in size, allowing very small sample volumes ranging from $10^{-9}$ to $10^{-18}$ [70]. Besides the small sample volumes that can be used with microfluidic devices, they are capable of faster separation time [70]. With ultra-small sample volumes being used with microfluidic devices, the challenge is that they must be coupled to very sensitive detectors. As with most traditional separation techniques, microfluidic devices have been coupled to conventional detectors such as laser-induced fluorescence, electrochemical detection, and mass spectrometry, but also non-traditional detectors including infrared, Raman, nuclear magnetic resonance (NMR), surface plasmon resonance, absorbance, and chemiluminescence detectors [70]. However, many of the detectors being used with microfluidic devices are the bulk detectors (emphasizing only the separation component is small), but recent work by Mecker and Martin integrated an electrochemical detector on a chip for dopamine analysis [71].

Microdialysis is a technique that generates samples with low volumes, and as a result there is great interest in coupling microdialysate samples to microfluidic devices. Microfluidic systems or "lab-on-a-chip" refers to the miniaturization of the analytical system for separation and measurement of analytes of interest. Although still in the beginning stages, it is anticipated that, microfluidic devices could successfully and quickly separate many analytes with low solvent requirements and minimal sample volume [69]. Current studies employing microdialysis and microfluidics monitor classical neurotransmitters such as amino acids and peptides. It is hoped that the future format for microfluidic devices will be able to analyze a wider variety of analytes or perform various assays in parallel [72–75]. Sandlin et al. of the Kennedy laboratory have already produced one of the first papers demonstrating the successful coupling of microdialysis and microfluidics [75]. Their online technique using a microfluidics electrophoresis chip with detection via laser-induced fluorescence allowed for the detection of various amino acid neurotransmitters in the rat brain [75]. Future work with microfluidics will hopefully build upon the promising potential of this form of electronic separation.

## 2.4 Detectors

Following collection of the dialysate sample, the molecules of interest are separated via HPLC or CE, and then the analytes of interest are detected and quantified. In general, detectors for microdialysis should possess the following characteristics: sensitivity (concentration of low nanomolar or less), stability, reproducibility of signal response, linear response to the analytes of interest, short response time, high reliability, and ease of use [57]. The three most commonly used detectors are electrochemical, fluorescence, and MS, detectors with low detection limits and selectivity of compounds. Interestingly, each one is used predominantly for a particular class of neurotransmitters. For example, electrochemistry is used for biogenic monoamines (including norepinephrine, dopamine, and serotonin),

fluorescence is used for the amino acids (GABA and glutamate), and mass spectrometry is used for neuropeptides.

***2.4.1 Electrochemical Detection of Analytes*** Electrochemical detection is favored for biogenic amine neurotransmitters because it can achieve exceptionally low detection limits (high picomolar) and it is selective for electroactive species. Monoamine neurotransmitters are found in very low concentrations in the brain extracellular space (typically <5 nM, not corrected for probe recovery). These species are oxidized (lose electrons) easily (at $\sim +600$ mV versus Ag/AgCl reference electrode), which makes them suitable analytes for electrochemical detection, as opposed to other neurotransmitters such as GABA and glutamate. The most widely used methods for electroactive biological compounds, like neurotransmitters, are amperometric and coulometric methods [76]. Amperometry and coulometry measure the change in the current generated during the oxidation or reduction of an analyte. In an amperometric system, the analyte of interest is allowed to flow either parallel or perpendicular to the working electrode in a thin layer configuration. The parallel cell design results in 5–10 % oxidation of the analyte to efficiencies approaching 100 % in the end-on perpendicular design, particularly when the latter is coupled to narrow-bore HPLC columns (i.d. <1 mm). Amperometric and coulometric detectors are roughly equivalent with respect to signal to noise (S/N) ratio. The coulometric detector utilizes an electrochemical cell which consists of three electrodes; a working electrode (oxidation), a counter electrode (reduction) and a reference electrode. In this design, the working and counter electrodes are composed of porous graphite which allows the mobile phase to flow through, oxidizing approximately 100% of the analyte. The potentials at each of the electrodes are held constant and as the analyte of interest is oxidized at the working electrode, a change in current is generated. The integrated current is the charge and this is proportional to the amount of analyte as explained by Faraday's law.

The applied potential for analysis of a multicomponent sample is a balance between maximizing the oxidation of the analytes of interest, while minimizing the oxidation of species that may interfere with analyte detection [57]. The identity of each neurotransmitter and metabolite is confirmed using known standard solutions to determine the retention times of each analyte. Standard curves bracketing the expected concentration for each analyte should be established before collecting dialysate samples. Calibration curves are based on peak areas of the known standard concentrations calculated by integrating peaks using current software. Sample peaks are then integrated and the peak areas are regressed to standard curves to determine their concentrations.

***2.4.2 Fluorescence*** Fluorescence is based upon a molecule's ability to absorb a photon and be promoted to a higher energy state, known as excitation. The fluorescence signal is observed when the molecule relaxes back to the ground state, releasing the photon which is then detected, a process is known as emission. Molecules that fluoresce easily are fused ring structures with a diffuse $\pi$ bonding system, a property easily applied to amino acid neurotransmitters, though the majority

of animo acids do not naturally fluoresce. The three amino acids that do have fluorescence properties are tryptophan, tyrosine, and phenylalanine, but to make the other amino acids fluoresce, a process known as derivitization is used. In derivatization, a fluorophore is covalently bound to the primary amine, allowing for the detection and quantification of amino acids by fluorescence. There are a number of pre-column derivitization compounds including 1-dimethyl aninoaphthaldenesulfonyl chloride (DANSYL), phenylisothiocynanate (PITC), 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate (ACQ), orthophthaldialdehyde/β-mercaptoethnaol (OPA-β-MCE), and naphthalene-2,3-dicarboxaldehyde/cyanide (NDA/CN), of which the two most popular derivitization compounds for the amino acids are OPA-β-MCE and NDA/CN. This is due to their stability and their native ability not to fluoresce. NDA is the slightly more favored derivitization agent due to its ability to provide higher quantum efficiency and enhanced stability [77].

Fluorescence can be easily coupled to HPLC or a CE system to detect analytes of interest from dialysate samples. When using a HPLC system, fluorescence is measured using a commercially available fluorescence detector. However, when using CE, a laser must be used as the source for measuring fluorescence [16,25,65,66]. In both cases a light source (lamp or laser) are used to promote the analyte of interest from the ground state to the excited state. When the molecule of interest falls from the excited state to the ground state, the resulting emission is measured. Fluorescence is a popular detection scheme for neurotransmitters due to its low concentration detection limits (~100 fM), mass detection limits (~10,000 molecules), high selectivity, broad detection range, high sensitivity, and high selectivity [25]. Additionally, fluorescence is being employed as a detector in online capillaries, off-line capillaries, and microchips, which provides an additional element of versatility.

The routine separation scheme for dialysate samples in the neurosciences includes use of HPLCs. However, there are drawbacks associated with HPLC separation, including poor mass sensitivity, large sample volumes required (leading to lengthy dialysis sampling times), and ultimately poor temporal resolution. As a result of these drawbacks, researchers have been developing CE separation techniques with fluorescence to detect amino acid neurotransmitters. Examples include coupling CE-laser induce fluorescence (LIF) with microdialysis, to make measuring small dialysate fractions (nL) and detecting low concentrations feasible. The Kennedy group has demonstrated rapid sampling of amino acid neurotransmitters in less than 10 s using CE-LIF, which greatly enhances the temporal resolution of the dialysate sample [78]. If microdialysate samples are collected off-line, this would require handling of very small fractions (nanoliters), which are susceptible to evaporation. However, if these samples were to be measured online, successful derivatization and separation must occur on a compatible time scale to accomplish the high throughput required (sampling ~6 s, would generate ~600 samples) [50].

***2.4.3 Mass Spectrometry*** MS is a powerful analytical technique that is capable of providing the element composition of samples and the structure of compounds, as well as qualitative and quantitative composition [57]. Unlike

electrochemical or fluorescent detectors, MS can in principle be applied to analyze any analyte of interest. MS is capable of precisely measuring the molecular mass of a compound, and can also be used to determine the sequence of a biomolecule [50]. MS is a destructive technique which ionize components of a sample, which in turn are separated using electric and/or magnetic fields. The mass spectrum demonstrates the resulting abundance of *mass-to-charge ratio* (*m*/*z*). Although MS destroys the sample in the process, sensitivity is high and little sample volume is required [79,80]. During the 1990s MS underwent an explosion of growth, providing key advances in biological research by providing high precision of structure and molecular mass [79,80]. During this time, MS became more amendable to measuring proteins and peptides due to improved ionization methods such as electrospray ionization (ESI) and matrix-absorbed laser desorption/ionization (MALDI) [79]. Although both methods are critical for evaluating and identifying key biopolymers, the focus of this mass spectrometry section will be on ESI. This is because MALDI is used for tissue analysis of proteins and is unable to discriminate between intracellular and extracellular tissue levels, and thus is not used in *in vivo* microdialysis sampling.

ESI is an ionization method which produces multiply charged ions. These ions are generated in a strong electric field, which induces charge accumulation, producing multiply charged droplets. Typically, ESI is coupled to a separation technique such as HPLC, capillary LC, nano-LC, or CE, and the sensitivity of ESI is dependent on the separation mode being used. Separation techniques with flow rates in the microliter to nanoliter per minute range offer enhanced sensitivity by increasing the sample's concentration in the elution solvent [79]. ESI is a very powerful method which permits the molecular weight determination of biomolecules, with very low detection limits reported to be in the attomole range [25,79].

Once the analytes have been ionized, they are ready for structural analysis or selective detection of a specific class of compounds by tandem MS (or abbreviated as MS/MS or $MS^2$) [79]. For example, the first mass spectrometer is used to isolate the precursor ion, while the second mass spectrometer analyzes the products [79]. There are many advantages of using tandem mass spectrometry on complex biological samples like microdialysis. These include the speed of isolation, sequence specific detection, and quantification of unknowns. In theory, tandem MS could be used for any peptide [16]. The most common mass analyzer is the quadruple analyzer, composed of four parallel rods that are opposite frequency or charge.

Currently, over a hundred known neurotransmitters have been identified, but not all of these neurochemicals can be detected by electrochemical or fluorescent detection. Of the neurochemicals available for analysis, mass spectrometry is typically used to evaluate *in vivo* neuropeptide levels. These samples are particularly challenging; they are present in low concentrations, sample size is small, and numerous similar compounds can contaminate the sample. Only within the last 20 years has mass spectrometry been directly coupled to microdialysis to determine the extracellular concentration of a small peptides [24,25]. The first few experiments with microdialysis coupled to mass spectrometry were analytically challenging, but much progress has been made. By coupling MS and microdialysis together, this can provide

an important first step for *in vivo* monitoring of neuropeptides, an underrepresented area of research at this time.

Neuropeptides are probably the most important biological molecules in the central nervous system (CNS). However, their low levels *in vivo* and their complex chemical structure make them difficult to be detected and analyzed with electrochemical or fluorescent detection. Although MS can be used to evaluate traditional neurotransmitters such as the monoamines and amino acids, its primary role with regards to microdialysis is to measure more challenging neurotransmitters such as acetylcholine, purine and pyrimidine bases, anandamide, and prostaglandins [24]. MS has been particularly useful in identifying extracellular concentrations of endocannobinoids, substance P, and neuropeptides such as neuroensin and met-enkephalin. Although the study of these neurochemicals is a developing field, understanding neuropeptides and other non-traditional neurotransmitters may prove important for future work with both traditional and non-traditional neurotransmission.

With the increasing popularity of microbore and capillary LC in recent years, there has been an increase desire to couple these separation components to MS. Sensitivity of the analytes detected by MS is currently in the picomolar range. With increased improvement of the HPLCs, such as ultra flow and nanoflow LC, this will add another dimension and enhancement to mass spectrometry analysis, enhancing its use in the microdialysis field.

## 3 MICRODIALYSIS SAMPLING APPLICATIONS

### 3.1 Introduction

With over 14,000 publications in the area of microdialysis ranging from neurochemical alterations following drug administration to pharmacokinetics of exogenous compounds, it is clear that microdialysis measurements can be made in virtually any tissue or organ. Although a comprehensive in depth coverage of the applications of microdialysis is beyond the scope of this chapter, we do highlight a few key neurochemical applications in this section.

### 3.2 Biogenic Amines and Amino Acids

Biogenic amines such as histamine, tyramine, dopamine, epinephrine, serotonin, and tryptamine are a class of compounds which contain an amine group. Dopamine is one of the most well studied neurotransmitter systems because of its involvement in the brain reward pathway (drug abuse/addiction), neuropathological conditions such as Parkinson's Disease, schizophrenia, attention-deficit hyperactivity disorder (ADHD), and Tourette's syndrome [81,82]. Dopamine is an ideal neurotransmitter for analysis as it is easily detectable in many brain areas and oxidizes easily. Under normal physiological conditions, DA is known to regulate locomotor activity, cognition, affect, and neuroendocrine hormone secretion [83]. Extracellular dopamine levels, which are easily measured with microdialysis, are a balance of release, uptake, and

metabolism. Release is controlled by many other neurotransmitter systems which terminate on to DA neurons, as well as feedback from the DA system itself. Termination of the DA signal is accomplished by reuptake by a 12 transmembrane protein known as the dopamine transporter (DAT) [83]. The primary function of the DAT is to inactivate extracellular dopamine by transporting it back into the cytosol. DA that remains in the synapse is broken down quickly by monoamine oxidase catechol-o-methyltransferase. All of these components of the DA system are the targets of diverse pharmacotherapies and areas of intense study.

Within the neuroscience community one of the most studied areas is the effect of illicit drugs on neurotransmitter systems. These include psychostimulants such as cocaine and amphetamines, CNS depressants such as opioids and alcohol, cholinergics such as nicotine, and inhalants such as toluene [84–87]. Some of the first microdialysis studies by Ungerstedt and colleagues examined extracellular dopamine levels in the striatum (caudate–putamen; CPu) in response to drugs of abuse. The authors were able to monitor behavioral responses to drug as well as monitoring neurotransmitter responses in real time in freely moving animals. For example, one study examined the acute response to amphetamine, and the subsequent microdialysis demonstrated that this effect was due to a potentiation of dopamine in the striatum [4,5]. Microdialysis experiments have also demonstrated that an intraperitoneal (i.p.) injection of cocaine elevates extracellular DA levels by $\sim$ 200% in the caudate–putamen and nucleus accumbens. Microdialysis continues to provide valuable information on the mechanism of action of drugs of abuse such as cocaine, ethanol, and amphetamines, and will continue to be important in understanding how the brain reacts to acute and chronic drug administration.

One of the most well characterized genetically altered mouse models is the dopamine transporter knockout mouse (DAT-KO) developed in the Caron laboratory in the mid-1990s [88]. Without the DAT, DA cannot be recycled back into the intracellular storage pool, leading to a deficiency of intracellular DA. An excess of extracellular DA leads to a hyperactive phenotype. The DAT-KO mouse, coupled to *in vivo* microdialysis, has been particularly useful in evaluating the DA system with respect to the molecular mechanisms of drugs of abuse (cocaine, amphetamine, and ethanol), dopaminergic neurotoxins such as 6-hydroxydopamine (6-OHDA), and 1,2,3,6-tetrahydro-1methyl-4-phenylpyridine (MPTP), and neurological disorders such as ADHD and Parkinson's disease.

DAT-KO mice treated with $\alpha$-methyl-*p*-tyrosine, a potent irreversible inhibitor of tyrosine hydroxylase, acquire Parkinson's disease like symptoms including tremors and rigidity [89]. Parkinson's disease is a neurological disorder that is characterized by a severe deficit in striatal DA [90]. Extensive degeneration of DA neurons and changes in other neuronal subpopulations leads to bradykinesia, rigidity, resting tremor, and postural instability. When DAT-KO mice were administered $\alpha$-methyl-*p*-tyrosine, their striatal DA levels showed significant decreases 20 minutes after treatment and a behavioral phenotype of Parkinson's followed [89]. These Parkinson-like symptoms were reversed by administering amphetamine derivatives, specifically 3,4-methylenedidoxymethampphetamine (MDMA) [89], which releases DA into the extracellular matrix. However, when DA dialysate levels were evaluated, there was no

recovery of extracellular DA levels following the administration of MDMA. The MDMA microdialysis data indicate that pharmacological activation of non-DA neuronal pathways may offer another option in restoring movement in Parkinson's patients [89]. This is only one example of the many microdialysis studies on DA systems, which have illuminated mechanisms of drug abuse, as well as mechanisms of movement disorders such as Parkinson's.

## 3.3 Neuropeptides

Small peptides are an important sub-group of neurotransmitters (neuroactive peptides). These are distinguishable from animo acid and monoamine transmitters, and tend to co-localize with these more prevalent neurotransmitters [24]. Currently, there are over 100 known neuropeptides such as endorphins, enkephalin, growth-hormone, releasing hormone, neurotensin, and somatostatin. Typically, neuropeptides are as fast acting as classical neurotransmitters and play a more modulatory role in the central nervous system [24]. Neuropeptides are also larger in size and present in lower levels than classical neurotransmitters, making electrochemical detection a challenge.

The number of microdialysis studies evaluating neuropeptides levels or identifying novel neuropeptides has increased over the last 5 years. For example, Haskins et al. successfully measured non-opioid peptides derived from proenkephalin A [23]. Microdialysis samples are taken directly from the extracellular space and discriminate based on molecular weight cutoff. Thus, the dialysate sample may have a complex array of small neuropeptides, and this can be particularly challenging when concentrations of neuropeptides are low and a finite amount of sample is available. To overcome these challenges, various database programs such as SEQUEST, Mascot, and Lutefisk are used to analyze the samples and provide a true representation of the analytes in the sample [23]. All together, Haskins et al. found 29 peptides from six different proteins including fragments from the brain acidic membrane protein NAP-22, neurogranin, fibrinogen, proenkephalin A, and peptide I 1-12 [23]. Much more work remains in the area of neuropeptides, and improvements in microdialysis technique will aid in discovery and analysis of these modulatory neurotransmitters.

## 3.4 Pharmacokinetics

As discussed so far in this chapter, microdialysis is a technique which can allow neuroscientists to monitor neurotransmitter release, uptake, and metabolism *in vivo*. An equally important area for microdialysis is monitoring the pharmacokinetics of compounds *in vivo*. Pharmacokinetics is the study of absorption, distribution, metabolism, and elimination of biologically active compounds in an organism. Typically, pharmacokinetic data are obtained by administering exogenous compounds and evaluating absorption, distribution, and metabolism in blood and/or tissue at specific time points. However, these experiments involve large numbers of animals, often have poor temporal resolution relative to the physiological or pharmacological events, and involve significant sample preparation time [10]. Finally, the

results obtained from tissue content pharmacokinetic studies do not discriminate between the intra- and extracellular concentrations of exogenous analyte, and thus cannot differentiate the amount of drug taken up from cells versus the amount in the extracellular space.

Using *in vivo* microdialysis to evaluate pharmacokinetics of biologically active compounds has many advantages over typical blood and tissue analyses. As previously discussed in this chapter, microdialysis discriminates molecules by molecular weight, and by this virtue provides fairly clean samples with no large macromolecular contaminants such as proteins or enzymes [10]. Once the dialysate is collected there is no further breakdown of analytes, since enzymes are excluded by molecular weight [10]. Microdialysis involves the constant perfusion at the region of interest, where there is no net loss of fluid from the organism, and analytes are monitored continuously at the site of interest [49,91]. Microdialysate samples contain only the free fraction of the biological compound of interest; hence microdialysis monitors only the extracellular levels of the compound of interest [49]. Although the topic of this chapter has focused mainly on the brain, virtually any tissue or organ can be monitored with the correct microdialysis probe [49]. Thus, one can imagine simultaneously sampling from a multitude of sites within the body to monitor drug pharmacokinetics. Another unique advantage of microdialysis is different parts of the same tissue can be monitored simultaneously. For example, many studies have focused on evaluating both the blood and the brain to examine transport kinetics of a biologically active compound across the blood brain barrier [92]. Using microdialysis to monitor pharmacokinetics allows a variety of experimental designs to be employed. For example, a within subject design can be used, where baseline is monitored prior to drug exposure. This allows each animal to serve as its own control, decreasing the number of animals required and minimizing the variation due to individual differences [20,21,49]. Pharmacokinetic microdialysis experiments using a within subject design include (1) acute or chronic drug administration, (2) dose-ranging studies, and (3) simultaneous measurements from the same tissue or organ [20]. With continuous monitoring, multiple sites (tissue/organs), or multiple analytes (endogenous or exogenous) generates a large amount of data. This large amount of data provides a more complete picture of absorption, distribution, metabolism, and excretion compared to single time point studies. Thus, microdialysis provides one of the best methods for studying pharmacokinetics in the living organism.

## 3.5 Blood and Tissue

Microdialysis was originally developed to analyze biological endogenous and exogenous compounds in the brain, and so many advances in the technique have been developed for brain-specific studies. But the brain is not the only tissue that can be sampled using microdialysis, and with the development of non-concentric probes many other organs and tissues have been evaluated using *in vivo* microdialysis, including blood, heart, liver, bile, kidney, skin, ocular, adipose, tumor, and muscle [49,93]. A comprehensive review of all the available microdialysis methods in organs and tissue is beyond the scope of this chapter. However, we have highlighted

some of the most recent studies of microdialysis in blood, liver, myocardium, bile, and stomach, to provide examples of recent work which highlights the multiple uses of microdialysis.

When microdialysis is used as the sampling technique to monitor analytes in the blood, the microdialysis probe is commonly implanted in the right atrial junction, providing a larger blood pool around the probe [94,95]. Microdialysis sampling of blood has the advantages of providing continuous sampling over time, as opposed to blood draws, which are time point specific. To better understand the pharmacokinetics of the antibiotic cefsulodin, Tsai et al. monitored the blood and brain levels of cefsulodin [96]. A recent study by Zolkowska et al. used *in vivo* microdialysis to examine serotonin (5-HT) plasma levels in non-hypoxic rats, following chronic treatment with the anorectic drug fenfluramine and the anti-depressant fluoxetine [97]. The goal was to determine if chronic administration of these drugs elevates plasma 5-HT levels. Zolkowska et al. demonstrated elevated plasma 5-HT levels in Sprague-Dawley rats following chronic administration of fenfluramine, although the levels were much below the micromolar levels that produce adverse cardiovascular functions [97].

The liver is one of the most commonly transplanted tissues. This is partly due to the fact that part of the liver can be transplanted to restore liver function, allowing for live donation. However, there is a risk that donated liver tissue may be dysfunctional, and that the recipient may reject the organ. Richards et al. employed *in vivo* microdialysis to monitor liver grafts through post-reperfusion to give indication of poor or non-functioning grafts [98]. Richards et al. found that none of the patients in the population exhibited poor or non-functional grafts, but the study demonstrated that microdialysis is important for characterizing metabolic changes from pre- to post-transplant grafts [98]. Bergström et al. has also developed a novel microdialysis method to follow known and unknown compounds in a model of liver disease, the first time that unknown analytes were followed in evaluation of a disease state [99]. By employing mass spectrometry and chemometric data evaluation, Bergström et al. discovered new biomarkers and biomarker patterns in a model of induced liver damage [99].

In 2004, Bahlman et al. used *in vivo* microdialysis to evaluate myocardial lactate and pyruvate concentrations in patients undergoing coronary artery bypass grafting and valve surgery [100]. This represented the first time that microdialysis was performed in humans with commercially available microdialysis catheters. Bahlmann et al. measured the lactate and pyruvate levels before, during, and after the cardiopulmonary bypass, and these compounds were shown to be sensitive markers of the myocardial redox status [100]. Thus, microdialysis has provided another tool to evaluate biologically relevant molecules during coronary artery bypass, and may prove to be a vital component of patient monitoring.

Tumors are another area where microdialysis has made inroads in patient monitoring. Most often patients must undergo tumor biopsy to determine whether a mass is benign or malignant. However, this does not provide details regarding the extracellular matrix or the pharmacokinetics effects of anti-tumor drugs. Implantation of a microdialysis probe directly into the tumor mass allows for both drug concentration and metabolism to be monitored, though this procedure is more invasive and

time consuming for the patient. A recent study by Apparaju et al. evaluated the anticancer agent gemcitabine in tumors and tumor-free regions of the brain to better understand the pharmacokinetic behavior of the drug in the CNS [101,102]. Their studies demonstrated that extracellular levels of gemcitabine were lower in tumor-free tissue compared to tumor tissue, suggesting that the tumor exhibits higher drug uptake. Microdialysis is thus an underutilized area of study in cancer research, though more work will surely be done as inpatient methods improve.

## 4 COMPARISON TO OTHER *IN VIVO* METHODS

Microdialysis is not the only *in vivo* method available to quantitate extracellular neurotransmitter levels in the brain. Positron emission tomography (PET) and voltammetry are two other neurochemical methods typically used. PET, a minimally invasive technique, and voltammetry, a more invasive technique will be discussed below. Each of these techniques provides advantages and disadvantages over microdialysis, but all of these methods offer an important glimpse into the neurochemistry of the brain. Work in all of these techniques will hopefully lead to better understanding of neurological diseases and disorders, with a view to creating improved treatments and therapeutics.

### 4.1 PET Imaging

PET imaging is a non-invasive *in vivo* imaging technique which uses radioactive ligands to measure *in vivo* metabolism. In a PET experiment, a small amount of radioactive analyte is administered to the subject. The subject is then placed in a ring of detectors for the $\gamma$-rays that are emitted when the positrons of the radioactive isotope collide with electrons *in vivo*. The information obtained through PET imaging is similar to the *in vitro* technique of autoradiography a spatial map of radioactivity distribution within the tissue [102]. PET has advantages over autoradiography in that it is non-invasive allowing for it to be used in clinical research, while autoradiography is an end point, measuring receptor or transporter levels *in vitro*. PET imaging has a spatial resolution of 3–12 mm compared to a few 100 μm for autoradiography [102]. Although autoradiography has improved spatial resolution, PET imaging done *in vivo* allows for longitudinal studies across the same individual [102]. One major hurdle for PET imaging is the synthesis of the radioactive ligand. In PET imaging, radioisotopes are substituted for one of the atoms making up a common drug, which can then be administered to a patient. Some examples include oxygen-15 ($^{15}O$), nitrogen-13 ($^{13}N$), carbon-11 ($^{11}C$), and fluorine-18 ($^{18}F$). The typical half life of these isotopes is between 2 and 109 min [102]. The short half life of the isotopes used means that temporal resolution is fairly high, usually a few minutes, though continuous monitoring of the patient must take place for as long as the radioactive ligand is available [103].

Synthesis of the positron-emitting radioisotopes used in PET imaging takes place in a cyclotron (a particle accelerator which promotes charged particles to higher

energies) [102,103]. The radioactive ligands are administered to the patient in very small doses, to prevent possible side effects associated with radioactive compounds. When the isotopes reach the tissue of interest, positrons are emitted from the radioactive ligand as it binds with receptors in the area. The positrons do not travel far (~ a few millimeters) before they collide with electrons present *in vivo* (annihilation), and the result is two high intensity γ-rays (photons) traveling in opposite directions. Detectors for the γ-rays are situated in a ring around the subject, and the γ-rays that arrive at near-simultaneously at completely opposite detectors are measured ("coincidence detection"). As a result complex algorithms are used to determine the quantification of the ligand binding that is taking place *in vivo*, which result in images with a high signal to noise ratio [102,103]. Although PET is very sensitive and non-invasive, it is a very expensive and time intensive technique with relatively poor spatial resolution, and as a result it is difficult to justify such huge expenses for rats or mice *in vivo*.

## 4.2 Voltammetry

Within the last 30 years there has been a surge in the development of biosensors to measure biologically relevant molecules *in vivo* (or *in vitro*). Biosensors offer fast temporal resolution (typically a measurement is made in a matter of seconds) and improved spatial resolution where a biosensor can be placed into small compartments or discrete brain regions. The biosensor field originated in 1956, with the development of the oxygen sensor patented by Leland Clark and has been used in medical and environmental research fields for measuring dissolved oxygen [104]. The oxygen sensor has served as the foundation for many of the biosensors in use today, such as the glucose meter [105]. Clark expanded on the oxygen electrode and developed a glucose biosensor by placing the enzyme glucose oxidase in between the membrane and the electrode [105]. Microdialysis has been in competition with biosensor techniques in recent years. Biosensors such as carbon fiber electrodes offer a few advantages over microdialysis enhanced/improved temporal resolution and a less invasive implantation [106]. Voltammetry is considered a biosensor technique because of its ability to detect only one neurotransmitter, as opposed to the complex mixture of analytes typically found in microdialysis.

Although there are a variety of electrochemical techniques to measure biomolecules such as amperometry, chronoamperometry, differential pulse voltammetry, and fast scan cyclic voltammetry (FSCV) the focus of this section will be FSCV. Electrochemical measurements provide another means for measuring biomolecules such as neurotransmitters. Monoamine neurotransmitters such as DA, serotonin and norepinephrine are easily oxidizable, which makes them ideal analytes for electrochemical detection. FSCV uses a microelectrode, which is a carbon fiber (length ~200 μm, diameter ~5 μm) enclosed in a pulled glass capillary to detect electroactive species. A triangle waveform is applied to the microelectrode in FSCV, initially the microelectrode is held at a constant potential versus a reference electrode (Ag/AgCl), then a rapid increase in potential is applied (forward scan) followed by an immediate

return (reverse scan) to the holding potential [107,108]. The potential of the working electrode is scanned between −400 and +1200 mV (versus Ag/AgCl), and the detection of the monoamines occurs at approximately +600 mV. Typically, fast scan rates (greater than 100 V/s) are used and the triangle waveform is completed in less than 10 ms allowing for electrochemical measurements to be made every 100 ms. An advantage of FSCV is that analytes are differentiated from one another based on their peak oxidation and reduction position.

In the work pioneered by Wightman and co-workers, electrodes are lowered into a brain region of interest and the release of DA and DA uptake are measured via oxidation and reduction of a carbon fiber electrode [109,110]. These measurements can be preformed in tissue slices (*in vitro*), anesthetized or freely moving animals to probe the dynamics of neurotransmitter signaling, which are known to occur on the time scale of milliseconds [111–116]. Voltammetry is the only bioanalytical technique that has the temporal resolution to measures changes in neurotransmitter concentrations on this time scale. Therefore, voltammetry is particularly useful for measuring changes in neurotransmission as a result of pharmacological or behavioral manipulations [107,117].

*In vivo* microdialysis work is most consistently compared with voltammetry work performed with carbon fiber electrodes, known as FSCV, a technique that has been in competition with microdialysis for the last 15 years. The carbon fiber electrode used in FSCV has a diameter of approximately 7 μm (20 times smaller than a concentric microdialysis probe), which allows the electrode to discriminate between the core and shell of the nucleus accumbens, a distinction that cannot be made when using microdialysis probes in a mouse model. Measurements are made within 15–30 s, a vast improvement over the minutes long analysis time of microdialysis. DA is the most common analyte measured using carbon fiber electrodes, as it is easily oxidizable and occurs in detectable levels in many brain areas. The limit of detection for carbon fiber electrodes is around 100 nM for DA, approximately 10 times the basal level observed using *in vivo* microdialysis. As a result of the poor limits of detection, an electrical stimulation must be applied to release enough DA in the general vicinity of the carbon fiber (*in vivo* anesthetized animals, see References [118–121]). However, recent evidence has indicated that fast scan cyclic voltammetry can measure burst firing *in vivo* with no electrical stimulation. Fast measurement and small size have helped FSCV gain in popularity, but there are limitations with the carbon fiber biosensor. Unlike microdialysis probes which discriminate based on molecular weight, carbon fiber electrodes are only able to measure one analyte based on its oxidation potential; there are no samples or separation components allowing for detection of multiple analytes. Currently, however, voltammetric methods are not sensitive enough detect basal neurotransmitter levels and chemical selectivity is poor. It is well understood that many neurochemical events are occurring simultaneously *in vitro* and *in vivo*, and voltammetry is limited to examining one neurochemical event at a time. Microdialysis offers the benefit of examining a number of chemically related molecules at the same time, at the sacrifice of temporal resolution (due to the length of time required to obtain a sizeable sample and the length of time necessary for analysis).

## 5 CONCLUSIONS

This chapter highlights some of the benefits and limitations of *in vivo* microdialysis in measuring biologically significant changes in various tissues, with a focus on the brain. *In vivo* microdialysis has been an established neurochemical technique for approximately 35 years, and many improvements can still be made with regards to technical aspects and appropriate data analysis and interpretation. Microdialysis has seen a surge in popularity over the last 15 years, partially due to the advent of genetically altered mice. However, there are two important drawbacks to *in vivo* microdialysis. Tissue damage cause by the probe is still an important limitation, as well as the inability to detect very small, but biologically relevant changes in neurotransmitter levels. These pitfalls have spurred new interest in developing "smaller" probes, such as capillaries that directly sample the extracellular fluid, to both reduce tissue damage and increase sensitivity [16].

The two most common *in vivo* bioanalytical methods for measuring neurotransmitter levels in the extraneuronal signaling space are *in vivo* microdialysis and *in vivo* or *in vitro* voltammetry. Microdialysis can be coupled to either HPLC or CE with electrochemical, mass spectrometry, or fluorescence detection, while voltammetry utilizes a carbon fiber microelectrode to stimulate release, oxidation, and reduction of analytes. Microdialysis has many advantages over voltammetry. It is sensitive enough to detect extracelleular neurotransmitter levels in the basal state. Further, analytes can be separated and identified by retention time or mass, allowing multiple analytes to be analyzed at the simultaneously. However, microdialysis sampling times are long (minutes) and semi-permeable microdialysis membranes are relatively large ($\sim$200 μm) with respect to sampling regions, especially in the mouse brain. The relative size of the probe can lead to significant damage in the region of interest [27,30]. Furthermore, determination of the recovery of neurotransmitters from the extracellular space is complex. Finally, in order to collect sufficient analytes to detect basal neurotransmitter levels, dialysate samples on traditional HPLC columns usually require 10–30 min of collection time. These long sampling times decrease the temporal resolution of *in vivo* microdialysis.

Voltammetry solves many problems of probe damage and temporal resolution. The dynamics of neurotransmitter signaling are known to occur on the time scale of milliseconds, and currently voltammetry is the only bioanalytical technique with the temporal resolution to measure changes on that time scale. However, only one chemical species can be monitored at a time. It is well understood that many neurochemical events are occurring simultaneously, and microdialysis offers the benefit of examining a number of chemically related molecules at the same time. Thus, when using microdialysis temporal resolution is sacrificed for chemical selectivity, multiple analyte detection, and analysis of basal neurotransmitter homeostasis. Recently, microdialysis coupled to CE separations has shown promise for reducing sampling times to seconds [122]. CE is highly advantageous for measuring neuroactive amino acids due to their high concentration in the extracellular space. However, measuring low nanomolar concentrations of the monoamines is much more difficult, and thus not all temporal resolution problems can be avoided [13]. However,

in cases where detections limits are adequate, coupling microdialysis to CE may allow *in vivo* microdialysis to compete temporally with voltammetry. Advances in analytical chemistry have also made it possible to measure low nano- to picomolar concentrations of biologically significant molecules using a variety of detection techniques, such as electrochemical detection, mass spectrometry, and fluorescence detection. If analytical chemistry continues to advance under the current philosophy of "smaller and faster", then real improvements for detecting temporally significant changes in neurotransmission will be achieved [16,78,123]. The future of the microdialysis probe is bright. It is the only technique currently available to measure basal neurotransmitter levels in the brain, and recent work has expanded microdialysis research to many other areas. Future experiments will only expand and improve the current techniques, resulting in new data and insights into brain and body, and elucidating the mechanisms responsible for disease and function.

# *Handbook of Analysis and Pharmaceutical Quality: Nano-Methods*

**Katherine M. Tyner**
*Food and Drug Administration, CDER/OPS/OTR/DAPR, Silver Spring, Maryland*

The views presented in this chapter do not necessarily reflect policy of the Food and Drug Administration. The mention of commercial products, their sources, or their use in connection with material reported herein is not to be construed as either an actual or implied endorsement of such products by the Department of Health and Human Services.

## 1 INTRODUCTION

Due to the unique features that arise from materials at the nanometer length scale, it is anticipated that nanotechnology will play a large role in emerging technologies, including those found in the pharmaceutical industry. The impact of drug delivery systems, nano-therapeutics, or combination products could affect treatment of disease by enabling targeted delivery or controlled delivery of therapeutics, which could minimize drug usage or decrease the frequency of drug use, while enhancing the safety profile (1,2). In addition, the ability to design multifunctional particles that can

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing,*
Edited by Shayne C. Gad

target, image and treat disease (3), protect fragile therapeutics from enzymatic and chemical degradation (4), and enhance bioavailability due to larger surface areas associated with smaller particles (5) can decrease the number of times a patient needs to be treated thereby boosting patient compliance and lowering treatment costs.

Nanotechnology and its many derivatives have numerous definitions from a wide range of sources (6), though a growing consensus, including the National Nanotechnology Initiative, is defining "nano" as containing features on the dimensions of 1–100 nm (7). The majority of US regulatory agencies including the Food and Drug Administration (FDA) have not, as yet, adopted a specific definition for nanotechnology and related materials[a]. Despite the lack of specific definitions, the FDA has in the past and is currently in the process of reviewing products that contain controlled features on the nanometer length scale.

With the expansion of nanotechnology into the pharmaceutical field, there has been increased pressure for adequate regulation and safety assessment of any resulting materials. Pre-clinical characterization as well as quality control during the manufacturing of nano-therapeutics is fundamental for understanding resulting safety issues stemming from product use. All regulated products are required to submit basic physio-chemical characterization as part of Investigational New Drug (IND) Applications or New Drug Applications (NDA) submitted to the FDA for review (8). Included in the characterization is proper identification of the therapeutic, including structure, composition, crystal structure, quality, stability, and purity, as well as the synthetic route of the therapeutic. Products containing nano-therapeutics are currently subject to all of the same regulatory review steps and characterization requirements that must be completed as a part of IND/NDA submissions for non-nano-material containing products.

Although nano-materials have always been present, the conscious directed assembly and enhancements available for nano-therapeutics may present novel safety and quality control concerns. In addition to the standard physio-chemical information, it has been proposed that products containing nano-materials should be additionally characterized to include information about particle morphology (size and shape), particle size distribution, surface effects (including surface area, reactivity, and coatings), and aggregation/agglomeration effects in relevant systems (9,10).

The unique features of nano-therapeutics can arise from multiple sources. Not only are surface features enhanced over bulk properties, but also size alone can affect biodistribution (11). Dissolution profiles can be altered (5,12), substantially increasing the bioavailability of traditionally insoluble drugs. Surface coatings can mask particles from the immune system or target hotspots in the body (2,3). These novel properties, if applicable to the nano-therapeutic, should be identified and noted for specific characterization.

In conjunction with the above determinations, particle state (aggregation/agglomeration effects) as well as particle morphology will be a key feature to characterizing the materials. Due to the high surface to bulk ratio for nano-materials and the

[a] For the purposes of this chapter, the prefix "nano" will refer to materials that contain at least one dimension ranging between 1 and 100 nm.

subsequent increased importance of surface effects, the raw nano-material may differ significantly from the formulated product. As a result, nano-therapeutics should be characterized in the final formulation in addition to any characterization of the raw material. Specific areas to consider are the aggregation/agglomeration potential of the therapeutic, potential interactions of the nano-material with the rest of the formulation, and changes in the nano-material over the course of its use. In the case of multifunctional materials, it may be desired that the nano-material changes over time (i.e., release of the therapeutic, targeting, degradation, etc.). In terms of multifunctional therapeutics, all components, their interactions with the material and the final formulation, and any potential release, intentional or not, should be examined in detail.

Table 1 details some of the physio-chemical analysis needed for therapeutics during the NDA/IND submission process as well as validation of methodology. Since some nano-therapeutics may be considered combination products, there may be additional considerations for these materials during characterization.

Determining how the nano-therapeutic can change, or if it can change other components of the formulation will play a major role in both characterization and quality control of the product. Although this type of characterization is required for all regulated materials, the characterization of nano-materials within a formulated product can be challenging in terms of appropriate instrumentation. The size and

complexity of nano-therapeutics can sometimes cause the resulting product to fall between the range and sensitivities of traditional instrumentation used for characterizing small molecules and/or bulk materials. Recent advances as well as application/modification of older technologies have emerged to address this issue, but there still can be shortcomings in terms of adequately characterizing different aspects of nano-therapeutics. In terms of quality control during manufacturing, equipment that has traditionally been available for nano-materials characterization may not be amenable to in-line processes, or may have long characterization times. There may, however, be methods that are adaptable from small molecule pharmaceuticals to nano-pharmaceuticals, and these methods need to be evaluated and validated for generalized use. In addition, if the instrumentation is not commonly used in an industrial setting, some of the concepts found in FDA guidances concerning method validation may need to be considered (13,14).

While the possibilities for novel nano-therapeutics are vast, the choices for characterization can also be quite extensive. Several key areas to focus on when choosing instrumentation include accuracy, precision, and detection limit of the instrument, as well as what type of information is being provided (bulk, statistical, image, etc.). There have been several review articles on basic nanoparticle characterization (15–18). The following chapter will provide an overview of methods typically used to characterize nano-materials specifically relating to the pharmaceutical industry, their relevance to the field, and what type of information is provided by the method. Figure 1 lists the acronyms used for this chapter.

## 2 INSTRUMENTATION OVERVIEW

Morphology has been, by far, the most common consideration when it comes to characterizing many nano-materials. While other properties may be as or more important than morphology, discussions about the size, shape, and related features of a product will factor into any subsequent characterization of nano-therapeutics. Morphological characterization can encompass not only the pertinent size and shape of a material, but also the size distribution of the features, and the aggregation/agglomeration status. It is important to remember that "nano" does not necessarily imply particle. The prefix "nano" has been used for particles, platelets, tubes, wires, or features on an extended material, and so on (19). Nano-materials can be individual moieties or embedded within a matrix, with each new feature able to impart different characteristics to the overall material.

In terms of determining size, it can be important to discriminate between primary particles, aggregates, and agglomerates, which can be defined as the following (20,21):

*Primary particle*: Individual crystals or discreet particles of a material.

*Aggregate*: Primary particles that associate during synthesis or post-synthesis conditions such that the overall surface area of the new moiety is reduced as compared to the individual primary particles. Aggregates will not revert back to primary particles under normal conditions.

***FIGURE 1*** *Common acronyms for nano-methods.*

*Agglomerate*: Loosely formed features made up of primary particles, aggregates, or a combination of the two. The overall surface area is not reduced, and the original particles can be recovered, depending on conditions.

Each of these features can contribute in different ways to the overall performance of a product (e.g., viscosity for agglomerates, surface reactivity for aggregates and primary particles). Depending on the product and application, therefore, it can become important to identify and characterize each size feature present in a formulation. Figure 2 shows various nano-entities.

For many methods, there will be a distinction between what type of information is provided by a particular instrument. Results can be a bulk average of the entire sample population or can measure individual, single, moieties. Both types of analysis have their advantages and disadvantages. Bulk measurements, on average, are rapid and more amenable to in-line analysis. They do not always, however, identify small populations of outliers that may be relevant for safety or quality control profiles. Instruments providing population profiles on single particles, while able to provide specific information for individual and small populations of a product, can have difficulty obtaining enough data to make statistically significant conclusions and can sometimes require lengthy analysis times. Figure 3 shows the results of a bulk method (DLS) and a single particle method (SEM) for 30 nm gold nanoparticles.

***FIGURE 2*** *Nano-materials may be individual entities or contained in a much larger material. Depending on conditions, primary particles can aggregate or agglomerate into larger entities.*

In general, compositional determination of the overall formulation, including the chemical composition, purity, and crystal structure of a material, will be possible using methods available for small molecule therapeutics (e.g., if crystal structure is needed, then X-ray diffraction would be an appropriate method to use). Characterization techniques such as ICP, IR, NMR, X-ray diffraction (XRD), and so on have already been discussed in previous chapters and will not be discussed further in this chapter.

***FIGURE 3*** *Size evaluation of gold nanoparticles by a bulk (DLS) method versus a single particle (SEM) method.*

a) Resolution is best possible. Sample and sample conditions may lower the achievable resolution.

In some cases, however, traditional small molecule analytical techniques may have special applications for nanotechnology (e.g., XRD used to determine the primary particle size of a nano-material). In other cases, techniques can characterize the composition of specific particles to allow for individual analysis of particles, which can become important for impurity analysis. Finally, other techniques are able to provide specific information about the surface of nano-materials. Techniques that provide specific nano-characterization will be discussed below. In-depth fundamentals of the methods are not provided and instead, the reader is referred to other reference books and papers, a partial list of which may be found in the following references (22–39, 49–51).

*A note on instrument resolution*: This chapter and the tables contained within it report the best achievable instrumental resolution at the time the chapter was written. Often sample or measurement conditions will lower the achievable resolution, sometimes quite dramatically. For example, SEM resolution can be as small as 5 nm. When introducing wet samples into an environmental chamber, however, the instrument may only be able to resolve 100 nm features. Thus, if resolution is important to a particular measurement, the effect that the sample and the sample conditions may have on the instrument resolution should be kept in mind when choosing analytical techniques. Often the introduction of moisture or pressure (i.e., environmental conditions) will lower an instrument's resolution capabilities. Table 2 lists the different microscopy methods and the type of information provided.

## 2.1 Microscopy

Microscopic methods are popular nano-methods as they often allow one to directly visualize individual moieties of the nano-material. Such visualization allows for extensive morphological evaluation. As individual particles are analyzed, the techniques usually provide statistics of individual size and shape populations of a material. The type of microscopy used will determine both lateral and depth resolution. In addition, many microscopies may be coupled with other techniques to provide compositional information.

***2.1.1 Electron Microscopy (EM)*** EM methods are prevalent in nano-material characterization due to their high resolution imaging capabilities. In each method, an electron beam interacts with a sample to produce an image. By utilizing results from different outcomes of the electron beam interacting with the sample, different types of information, including compositional, may be obtained. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) are the most common methods used, although modifications to each have produced a wide sub-set of instrumentation.

*TEM* (Transmission electron microscopy): A high resolution technique that provides an image of the sample. An electron beam is transmitted through a thin sample specimen. Regions where the electrons are scattered appear dark on the viewing screen. Samples are very thin ($< 100$ nm) and are often analyzed in high vacuum.

Attachments to TEM:

ED (Electron diffraction): Electrons from the TEM beam are scattered elastically to produce a diffraction pattern. By analyzing the pattern, crystal morphological information may be obtained. Small regions within the sample can be analyzed with this technique.

EELS (Electron energy loss spectroscopy): The energy loss of low-energy electrons hitting the sample is examined through an attached detector. The energy spectrum of the electrons provides information about the composition and structure of materials. Sub-nanometer resolution is possible with this method.

EDS (Energy dispersive spectroscopy): The electron beam interacts with the sample, causing electrons to be ejected from the inner shell of a sample's atoms, forming an electron hole. An electron from an outer shell fills this hole, causing energy release in the form of an X-ray. The X-ray spectral lines are characteristic for individual elements, allowing for compositional determination.

*SEM* (Scanning electron microscopy): A high resolution imaging technique whereby an electron beam is scanned over the surface of a sample. The interaction of the beam with the sample surface causes electrons to be scattered or absorbed, resulting in the emission of electrons and electromagnetic radiation that can be detected to produce images of the sample surface as well as used to identify elements within the sample. As the electron beam is interacting with the surface of the material, it is an inherently surface method.

Attachments to SEM:

BSE (Back scattered electrons): BSE are high energy electrons from the scanning beam that are reflected back out of the sample through elastic collisions with the sample and can be collected with a specific detector. An attribute of BSE is that the brightness of the image increases with atomic number, and thus high contrast may be achieved between components of different elemental compositions.

EDS: See TEM.

WDS (Wavelength dispersive spectroscopy): As with EDS, characteristic X-rays are produced from the electron beam interacting with the sample. How the X-rays are separated differentiates the two techniques. Typically, sensitivity is improved with WDS.

FIB (Focused ion beam): A sample is bombarded with an ion beam that is used to etch away the sample. As the sample is etched away, structural and compositional data can be obtained with SEM analysis from the removed layers or from the walls of an etched hole, providing morphological and compositional data in three dimensions.

EBSD (Electron back-scatter diffraction): This technique analyzes diffraction patterns of backscattered electrons. Patterns are analyzed to provide information on crystal phase and morphology of the material.

AES (Auger electron spectroscopy): The electron beam interacts with the sample, causing electrons to be ejected from the inner shell of a sample's atoms, forming an electron hole. An electron from an outer shell fills this hole, causing energy release in the form of an energetic electron. The energy of the electron is characteristic of elements, allowing for compositional information about a sample surface. Elemental identification, quantification, chemical states, and chemical reactivity are possible with this method.

SAM (Scanning Auger microscopy): An electron microscope specifically designed to analyze Auger electrons is used in this technique. High resolution compositional images may be produced. The method can be combined with sputtering to get in-depth profiles.

*STEM*: (Scanning transmission electron microscopy). This method combines the high resolution capabilities of a TEM with the scanning raster beam of a SEM.

Attachments to STEM:

EDS: SEE TEM.

EELS SEE TEM.

ADFI (Annular dark-field imaging): In this technique, a detector collects electrons that are diffracted, rather than transmitted. As with BSE, this technique provides contrast that is highly sensitive to atomic number.

***2.1.2 Scanning Probe Microscopy (SPM)*** SPM microcopies are also popular techniques used to analyze nano-materials due to their high resolution capabilities. In SPM, a cantilever is used to scan a specimen surface. Depending on the cantilever, sample conditions, and type of SPM, different properties of the sample may be measured under environmental conditions on a wide range of substrates. Atomic force microscopy is the most common SPM method used due to its high versatility in analyzing many different sample characteristics.

*AFM* (Atomic force microscopy): This method is a high resolution probe microscopy that can achieve atomic resolution by scanning or tapping a cantilever on or close to the sample surface. In addition to height imaging, forces, chemical bonding, and a wide variety of sample-probe interactions may be measured. Three-dimensional surface profiles may be obtained with this technique in contact, non-contact and dynamic modes. The samples can be imaged in a variety of environmental (including wet) conditions.

*STM* (Scanning tunneling microscopy): This method can achieve atomic resolution using quantum tunneling to construct three-dimensional images of a sample. Samples must be very flat and free from contamination. Samples must be either conductive or semi-conductive.

*NSOM* (Near-field scanning optical microscopy): A probe method that breaks the optical resolution of light by placing the detector close to the specimen surface in order to obtain the high frequency spatial information found in the evanescent fields close to the sample surface. Properties such as refractive index and chemical structure can be studied with this technique. Contrast techniques available for use with optical microscopy can be used with NSOM.

**2.1.3 Optical Microscopy (OM)** In general, OM methods cannot accurately size nano-scale materials due to optical resolution limits. Advances in some optics and illumination systems, however, can now resolve particles smaller than 100 nm (40,41). Even without the spatial resolution, if the nano-material has significant contrast over the background material/formulation, the particles can often be detected, if not sized. In some cases, this type of detection will allow for sufficient characterization. Such detection, coupled with some optical methods being able to examine materials in depth, may allow for bulk distribution analysis of the material.

*High Resolution Illuminator* (*Cytoviva®*): The standard microscope condenser is replaced by a high resolution illuminator with a fixed-geometry. The result is highly collimated light that is focused onto the surface, allowing for a high signal to noise ratio and a corresponding increase in resolution. This method maintains OM features, such as imaging in environmental conditions, while resolving individual nano-sized features.

*STED* (Stimulated emission depletion microscopy): The optical diffraction barrier is broken in far-field fluorescence confocal microscopy. Spontaneous fluorescent emission is inhibited at the periphery of the diffraction limited spot of a confocal microscope. This results in a fluorescent spot (effective point-spread-function) that is smaller than the diffraction limited dimensions, allowing for individual nanoparticle detection while maintaining confocal capabilities.

**2.1.4 Other Microscopy** *FIM* (Field-ion microscopy): A sharp metal tip is placed in an ultra high vacuum environment, which is then filled with helium or neon. The tip is cooled and a positive voltage is applied across the tip. Repelled ions are detected and form an image.

Derivatives of FIM:

- APFIM (Atom-probe field-ion microscopy): Time of flight spectroscopy is couple with FIM to allow for 3D reconstructions of samples with chemical profiles at the atomic level.
- IAP (Imaging atom probe): Ions emitted from the surface are mass analyzed by "time-gating" the detector. Crystal information and nano-material distribution can be determined.
- APT (Atom-probe tomography): A three dimensional atomic reconstruction of a surface can be generated by using a position-sensitive detector.

## 2.2 Scattering Methods

Scattering methods are also very common in the analysis of nano-materials. For the most part, these methods provide a bulk measurement. Depending on the method, assumptions about the sample (i.e., spherical shape for light scattering) are inherent in the measurement calculations. Many of the methods are easily automated. Table 3 lists the different methods and the type of information provided.

**TABLE 3 Information Obtained from Nano-Methods**

| | MORPHOLOGY | | | | | | Composition | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Instrument | Resolution[a] (nm) | Image | Shape[b] | Bulk Dispersion | Average/ Single | Environmental | Detected | Limit of Detection[a] | Lateral Resolution[a] | Bulk Comp | Surface Info | Crystal | Comments |
| **DLS** | 0.5 nm | N | N | Y | A | If solution based | | | | | | | Most calcs assume spherical shape. |
| **SLS** | 20 nm | N | N | Y | A | If solution based | | | | | | | Absolute molecular weight and concentration may be determined. |
| **PCCS** | 1 nm | N | N | Y | A | If solution based | | | | | | | Absolute molecular weight and concentration may be determined. Calcs assume spherical shape |
| **XRD** | <200 nm | N | Y, C | N | A | Y | | Depends on count time | | Crystal phase | | Y | Primary particles sized. |
| **SAXS** | 1–100 nm | N | Y, C | Y | A | Y | | | | | | | |
| **SANS** | 1 nm | N | Y, C | Y | A | Y | | | | | | | |
| **SIMS** | 20 nm | Y | Y | Y | Both | N | All elements | ppb | 20 nm | Y | Y | N | Inherently destructive. Needs special detector for imaging. |
| **SNS** | 50 nm | Y | Y | Y | Both | N | All elements | ppb | 50 nm | Y | Y | N | See SIMS |
| **FIB** | 5 nm | Y | Y | Y | S | N | | | | | | | Inherently destructive |
| **FFF** | 1–100 nm | N | Y, C | Y | A | If solution based | Surface funct | | | N | Y | N | Size limit and surface information dependent on sub-technique |

| | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| **AUC** | 1 nm | N | Y, C | Y | A | If solution based | | | | | | |
| **CHDF** | 10 nm | N | N | Y | A | If solution based | | | | | | |
| **XDC** | 5 nm | N | Y, C | Y | A | If solution based | | | | | | |
| **HPLC** | <1 nm | N | Y, C | Y | A | If solution based | Surface funct | | | Y | N | May not handle very concentrated systems. Surface info dependent on column |
| SEC | <1 nm | N | N | Y | A | If solution based | | | | | | |
| **AAS** | 5 nm | N | N | Y | A | If solution based | Surface charge | | | Y | N | Concentrated solutions are possible |
| **ATOFMS** | 30–300 nm | N | N | N | S | N | Charged species | 1–800 Da | N | N | N | Single particle analysis |
| **RS** | 1–100 nm | N | N | N | A | Y | molecular species | ppm | Y | Chemical bonding | Y | Primary particles detected. Lateral resolution of imaging is not in the nano range |
| **PGSE NMR** | 1 nm | N | Y, C | N | A | N | | | Y | Y | N | Dilue systems. Bulk compositional information with other NMR techniques |
| **DMA** | 1 nm | N | N | Y | A | N | | | | | | Aerosol based method. Dilute samples needed |
| **PHA UCPC** | 3–10 nm | N | N | N | A | N | | | | | | |

a) Resolution is best possible. Sample and sample conditions may lower the achievable resolution.
b) Calculations (C) used to determine shape effect on measurements.

**2.2.1 Light Scattering** Light scattering techniques, coupled with EM analysis, are probably the most common methods used to measure nanoparticles in a solution. The results are presented as an average size distribution, and for most methods, the calculations assume that the particle is spherical.

*DLS* (Dynamic light scattering): This is also known as photon correlation spectroscopy. This method uses scattered laser light to measure the diffusion of particles dispersed in a liquid. By utilizing the Stokes-Einstein equation (refer to Section .3), the hydrodynamic radius of the particle may be calculated.

*PCCS* (Photon cross correlation spectroscopy): This method is a modification of DLS and uses a three-dimensional cross correlation technique that suppresses multiple scattering of the laser light, allowing for high sample concentrations to be measured. Particle size and stability of suspensions may be obtained using this technique.

*SLS* (Static light scattering): This method measures light scattered by a particles in solution, often at a number of angles. The time averaged scattering intensities are detected at multiple angles, with the scattering pattern depending on the shape and size of the particles. The average radius of gyration is generated with this method. In addition, the intensity of the scattered light is proportional to the weight-average molecular weight and concentration of the particles.

**2.2.2 X-Ray Methods** *XRD* (X-ray diffraction): X-rays are diffracted from randomly oriented crystals in a sample, providing information on the sample's crystal structure. Polymorph identification and quantification may be obtained. In addition, if the primary crystallites are below ~200 nm, an estimate of the particle size and particle size distribution may be calculated through line broadening analysis.

*SAXS* (Small angle X-ray scattering): Elastic scattering of X-rays is recorded at very low angles (0.1–10°). Information about bulk particle sizes, shapes, distribution and surface to volume ratio may be obtained. Unlike XRD, a crystalline sample is not needed.

**2.2.3 Electron Scattering** See Electron Microscopy.

**2.2.4 Neutron Scattering** *SANS* (A complementary technique to SAXS): A beam of neutrons is elastically scattered off of a sample to determine structures between 1 and 100 nm. Particle size may be determined as well as size distributions. Size data are reported in the form of radius of gyration. A feature of SANS is its sensitivity to light elements such as hydrogen and carbon.

**2.2.5 Ion Scattering** *SIMS* (Secondary ion mass spectrometry): A sample surface is bombarded with an ion beam. The emission of entities from the surface (electrons, charged and neutral atomic and molecular fragments) are measured and analyzed by mass spectrometry.

*SNMS* (Secondary neutral mass spectrometry): Similar to SIMS, but ejected neutral atoms are analyzed after post-ionization.

*FIB* (Focused ion beam): A technique similar to SEM, but using an ion beam (usually $Ga^+$) rather than electrons. Sputtered ions or secondary electrons are collected to form an image. In addition, FIB can be used to flatten and mill samples for TEM analysis.

## 2.3 Separation Methods

Not surprisingly, separation techniques typically provide better resolution between different size populations of a sample. Different detection methods and detectors may impact the resolution and applicability of the measurement to nano-therapeutics. Table 3 lists the different methods and the type of information provided.

*AUC* (Analytical ultracentrifugation): In this method, a sample is spun and the concentration distribution in a centrifuge cell is monitored in real time through an optical detection system. Sample purity, shape, size, size distribution, and molecular weight may all be determined with this method.

*XDC* (X-ray disc centrifuge particle size analyzer): Gravitation and centrifugal sedimentation are combined in this method to allow for a narrow separation of particle population distributions. Particles are detected by X-ray attenuation.

*FFF* (Field flow fractionation): This method is solution based separation method where a solvent stream is introduced into a thin cell, with different forces applied perpendicular to the sample flow causing separation and sizing of a wide range of samples. Many varieties of this method exist, and some are listed below.

*Sedimentation*—The channel is spun resulting in a separation of the materials at a right angle to the sample.

*Thermal*—A temperature gradient is produced across the channel with particles driven to the colder side.

*Hydraulic*—A cross flow over the sample pushes particles to the channel wall, which is permeable. The pore size determines the lower size limit.

*Electric*—A potential gradient is placed across the channel, separating out species of different charges.

*Steric*—The opposite channel wall provides a steric barrier, with the smaller particles able to get closer to the wall than larger particles.

*CHDF* (Capillary hydrodynamic fractionation): This method flows a sample through a capillary tube. The particles elute out of the capillary tube based on their hydrodynamic radius, and are detected by a UV detector.

*HPLC* (High performance liquid chromatography): This is a form of column chromatography that pushes a liquid mobile phase through a stationary column. Depending on the column packing material, entities may be separated by polarity, size, surface charge, and so on. A detector monitors the retention time of the entities as they elute from the column.

*SEC* (Size exclusion chromatography): This is also known as gel permeation chromatography and may be part of an HPLC system. Particles are separated by their hydrodynamic volume.

## 2.4 Miscellaneous Methods

Table 3 lists the different methods and the type of information provided.

*AAS* (Acoustic attenuation spectroscopy): Also know as acoustic spectroscopy. The attenuation and sound speed of ultrasound pulses are measured over a wide range of frequencies. The generated spectra can be used to calculate particle size distributions.

*ATOFMS* (Aerosol time-of-flight mass spectrometry): This method uses a single particle mass spectrometry system that analyzes the size and chemical composition of single particles in aerosol form.

*RS* (Raman spectroscopy): A spectroscopic technique analyzing vibrational and rotational modes in a sample. Analyzing the line broadening and peak asymmetry in a spectrum can provide information about the particle size.

PGSE NMR (Pulsed gradient spin-echo nuclear magnetic resonance): The hydrodynamic radius of small particles in a dilute solution may be measured with this NMR method by measuring the self-diffusion coefficient. The concentration dependence of diffusion may also be determined with this method.

*DMA* (Differential mobility analysis): An aerosol based system that analyzes particles based upon their electric mobility, which is based on both size and charge.

*SMA* (Scanning mobility particle sizer): An aerosol based system used in conjunction with DMA to obtain a complete particle size distribution by scanning the voltage in the DMA system.

*PHA-UPC* (Pulse height analyzer ultrafine condensation particle counter): This is an aerosol method where supersaturated vapor condenses onto small nanoparticles and are detected and counted with an optical detector. Small aerosol concentrations may be determined.

***2.4.1 Bulk Surface Methods*** There are also several bulk methods that are commonly used to provide information about nano-materials. Included in these methods are various titrations for surface charge and surface functionalization.

*BET* (Brunauer, Emmett, Teller): A method named after the authors of the journal article describing the rules of gas molecule adsorption onto solid surfaces. Through application of their theory, specific surface area of materials may be measured.

*Zeta potential*: The electrostatic potential from ions on the surface of a colloidal particle (electrical double layer) is measured by a laser when a known E field is applied across a sample. Electrophoretic mobility is related to the velocity of particle movement, causing a frequency shift in the incident laser beam and allowing the zeta potential to be calculated.

*ESA* (Electroacoustic spectroscopy): This method is related to AAS. The electric and acoustic fields are measured in a sample to determine the zeta potential of the particles.

*GE* (Gel electrophoresis): An electric field is applied across a gel matrix. Compounds are separated out by electric charge and frictional forces.

*CE* (Capillary electrophoresis): Also capillary zone electrophoresis. An electric field is applied across a small capillary filled with an electrolyte. All ionic species are

pulled through the tube in the same direction by electro-osmotic flow. Separation is due to electrophoretic mobility, and moieties are typically detected by UV.

*SPR* (Surface plasmon resonance): An optical technique used to measure changes in the RI of a surface when different moieties bind to it. Binding interactions between different moieties may be examined with this technique.

## 3 NANO-METHODS: NOTES AND EQUATIONS

All analytical methods will have their benefits and limitations. Especially at the beginning of the characterization process, it is beneficial to compare two or more techniques to account for each instrument's suitability for analysis.

### 3.1 Microscopy

Microscopy methods allow for individual particles to be analyzed. While this data can provide specific details for the sample population, in order to gain statistical significance of the size values, a sufficient number of particles need to be analyzed. The number of particles needed to be analyzed depends on, among other things, the particle size distribution and the desired measurement error. There are specific algorithms that have been produced to determine the number of particles needed to be analyzed for statistical significance (42).

***3.1.1 Electron Microscopy*** EM methods are often surface techniques, with the analysis confined to the top layer of a material, or in the case of TEM, to a thin section of a sample. In order to analyze a sample in bulk, additional sample preparation is necessary. Such preparation could include FIB with analysis of removed layers, or cryogenic methods, followed by fractionation and cross-section analysis.

*3.1.1.1 Transmission Electron Microscopy* TEM is typically run under a high vacuum, so samples must be dry when analyzed. Although environmental TEM set-ups do exist, they are not yet common. Samples must be between 100 and 200 nm in thickness. For nano-materials that are embedded within a matrix or are part of a larger material, this restriction means that the sample must be cut or thinned. Techniques such as microtome procedures or FIB preparation can produce these thin samples. If the nano-material is in a liquid suspension, then a portion of the sample may simply be dropped onto a TEM grid and allowed to dry. Although this is a facile sample preparation, artifacts from the drying process, including a misrepresentation of the aggregation/agglomeration state may occur with this sample preparation. Cryogenically freezing the sample, followed by analysis with cryo-TEM will prevent such artifacts, but requires a cryogenic attachment to the TEM.

Less electron-dense materials (such as carbon based materials) do not deflect the electron beam sufficiently for a signal and often cannot be imaged well with TEM. Heavy metal staining procedures, such as using phosphotungstic acid can be used to

increase contrast in these materials. If surface groups attached to a core nano-material are carbon based (such as PEG, protein, or peptide surface coatings), these coatings may not appear in the TEM analysis, and the particle size will appear smaller than it actually is. Coupling TEM with another type of analysis, such as DLS, will help alleviate some of these errors as well as confirm that the portion of material analyzed (a small sample size inherent with the method) is representative of the entire sample.

*3.1.1.2 Scanning Electron Microscopy* Although this method has less resolution than TEM, the operation of the instrument is often easier and more amenable to high throughput analysis. Traditional SEMs run under a full vacuum. Environmental chambers (ESEM) allow for both humidity and pressure in the sample chamber to be controlled, thus allowing for formulated materials to be directly analyzed without having to dry the sample. Alternatively, cryogenic methods may also be used with this technique, if a cryogenic stage is available.

SEM samples are typically coated with a conductive coating to prevent charging of the samples (which reduces the resolution of the instrument). While environmental set-ups do not require a conductive coating, resolution will often be decreased if it is not present on the sample due to charging effects. In addition, soft samples may be damaged in the electron beam, resulting in measurement errors.

When coupled to EDS, a comprehensive picture of the formulation may be determined. A special detector is needed to provide elemental mapping images. Although EDS does not have the lateral resolution of SEM to make precise sizing measurements, often individual features and contamination can still be determined with these image maps.

***3.1.2 SPM*** SPM methods can be extremely versatile, with the limitations of analysis being the measurement modes, the attachments to the instrument, and the probes used. As with TEM, however, only a small area is typically examined, which can lead to a non-representative portion of a sample being analyzed. In addition, artifacts from tip damage or the scanning method may complicate analysis. Lengthy and complex analysis as well as what can sometimes be a long optimization process to obtain images does not always lend SPM methods to be the first line of analysis. SPM methods, however, can provide otherwise inaccessible sample information, and analysis and imaging parameters, once optimized, can even become automated (43).

***3.1.3 Optical Microscopy*** The achievable resolution of most optical microscopes follow:

$$d = \frac{\lambda}{2A_n}$$

where $d$ is the resolution, $\lambda$ the wavelength of light, and $A_n$ is the numerical aperture of objective lens.

With the exception of some notable examples (refer to Section 2.2.3), most optical scopes will not be able to resolve nano-scale features. Depending on the conditions, materials, and microscope set-up, nano-scale features might be able to be detected, if not accurately sized. This type of information may be sufficient for some types of analyses. Most OM methods are either environmental or may be easily set-up to allow for a wide variety of environmental settings. In addition, OM may encompass a wide range of methods including fluorescent microscopy and all its related techniques and confocal microscopy. Confocal microscopy makes use of pinhole geometry to selectively focus on a single optical plane in a sample. By collecting stacks of optical planes in the $Z$ direction, a three-dimensional representation can be constructed with little or no modification made to the sample, allowing for in-depth, three-dimensional analysis.

## 3.2 Scattering Methods

Unlike microscopy evaluations, particles are not directly visualized when using scattering methods. Instead of measuring feature sizes, particle characteristics are often determined through well-established equations.

### *3.2.1 Light Scattering*

*3.2.1.1 Dynamic Light Scattering* If particles interacting with light are sufficiently smaller than the wavelength of the light they are scattering, the light is scattered by the particles uniformly in all directions. This type of scattering is called Rayleigh scattering (for larger particles roughly above 250 nm, Mie scattering dominates, which is angle dependent). Due to Brownian motion, the particles are in constant motion, and the intensity of the fluctuation of the laser light due to the particle interactions can provide the diffusion coefficient, which can then be placed into the Stokes–Einstein equation:

$$D = \frac{k_b T}{6\pi\eta a}$$

where $D$ is diffusion constant, $k_b$ the Boltzmann constant, $T$ the temperature (in Kelvin), $\eta$ the viscosity of the solvent, and $a$ is the hydrodynamic radius.

Historically, DLS systems could only measure particles in highly dilute systems. This limitation was mainly due to the multiple scattering of laser light in concentrated systems. Advances in the technology, including the development of backscatter detectors, have extended the utility of this method to highly concentrated samples. Thus, most samples do not have to be diluted prior to evaluation.

Typical instruments will provide different numerical weightings of the sample size distribution as well as the polydispersity of the sample.

The polydispersity index of a sample can be expressed as

$$\varepsilon = \sigma/R$$

where σ is the standard deviation and $R$ is the average particle radius.

Depending on the application, the polydispersity index may become important. In many cases, a low PDI (more uniform) product is desired, although there are notable cases where a wide distribution of particle sizes is preferable (e.g., inorganic sunscreens).

In addition, the weighting applied to the particle size distribution can greatly influence interpretation of results. The most common weightings are number, volume, and intensity and scale as $n = 0$, 3, 6, respectively, for the following equation:

$$P_n(R) = \frac{R^n N(R)}{\int_0^\infty R^n N(R)\mathrm{d}R}$$

where $P_n(R)$ is the distribution, $N(R)$ the particle number density, $N(R)\mathrm{d}R$ the number of particles per united volume with radii between $R$ and $R + \mathrm{d}R$ and $R$ is the particle radius.

Intensity weighting tends to favor larger particles, thus if the sample has aggregates, these may appear as a larger fraction of the sample. The type of weighting used in DLS analysis should always be reported with the value.

Deviations from a sphere, misrepresenting the viscosity and refractive index of the dispersing medium, or having a sample that absorbs the laser light, cause the most common errors in DLS. In addition, agglomeration and settling of the material can cause measurement inaccuracies. As the method does not directly visualize the particle, however, the entire particle diameter is measured, including organic coatings that may not be taken into account with EM methods.

DLS results are presented as a bulk average of the tested solution, with polydispersity typically being calculated along with the weighted average size. Separate size populations that have similar sizes can sometimes appear as one large, broad, size distribution rather than two separate, narrow, populations. Modifications may be performed to standard DLS technique to increase the resolution between separate size populations, including first separating the particles through methods such as FFF or chromatography.

*3.2.1.2 Static Light Scattering* SLS measures the scattered light intensity as a function of scattering angle and concentration. Most instruments use the theoretical foundation set out by Zimm to obtain particle information from the intensity of the scattered laser light.

$$\frac{Kc}{R(\theta)} = \frac{1}{M_\mathrm{w} P(\theta)} + 2A_2 c$$

where $K$ is a constant, $c$ the concentration (g/mL), $R(\theta)$ the excess Rayleigh ratio (the

excess of light scattered in a solution per unit solid angle θ over the pure solvent, divided by the incident light intensity), $M_w$ the weight average molar mass, $A_2$ the second virial coefficient, and $P(\theta)$ is the Form factor of the material.

Since the form factor depends on the structure of the material, the radius of gyration as well as other structural information about the sample may be obtained.

### 3.2.2 X-Ray Scattering

*3.2.2.1 X-Ray Diffraction* X-ray diffraction patterns obey Bragg's Law:

$$n\lambda = 2d\sin\theta$$

where $n$ is the integer of the order of reflection, λ the wavelength of incident X-ray beam, $d$ the distance between atomic layers in a crystal, and θ is the angle of incidence.

Whereas the diffraction pattern is indicative of a certain crystal state, analysis of the individual peaks may provide additional information about the material. The Scherrer equation uses peak broadening to obtain approximate crystallite diameters. Calculation errors may be as high as 20%, and will increase if other factors, such as crystallite strain, are not accounted for.

The Scherrer equation analyzes the peak broadening at FWHM of a material's characteristic peaks. Before sample peak broadening can be analyzed, instrumental broadening must first be accounted for:

$$\mathrm{FWHM}^2_{\mathrm{observed}} = \mathrm{FWHM}^2_{\mathrm{instrument}} + \mathrm{FWHM}^2_{\mathrm{size+strain}}$$

Then the Scherrer equation may be applied:

$$D \sim \frac{K\lambda}{\mathrm{FWHM}_{\mathrm{size}}\mathrm{Cos}\,\theta}$$

where $K$ is the a unit cell geometry dependent constant (typically between 0.85 and 0.99), $D$ the particle diameter (volume weighted), λ the wavelength of incident X-ray beam, θ is the angle of incidence, and FWHM is in radians.

If strain is present in the system ($\mathrm{FWHM}_{\mathrm{strain}} = \eta\mathrm{Tan}\,\theta$, $\eta$ = microstrain), then the equation may be written as

$$\mathrm{FWHM}_{\mathrm{size+strain}}\mathrm{Cos}\,\theta \sim \frac{K\lambda}{\mathrm{D}} + \eta\sin\theta$$

The particle diameter and microstrain can be determined from a linear regression of $\mathrm{FWHM}_{\mathrm{size\,+\,strain}}\mathrm{Cos}\,\theta$ versus $\mathrm{Sin}\,\theta$.

By analyzing peak shape, height, and relative intensities, other properties of the crystallite may be calculated including shape and thickness (44).

*3.2.2.2 Small Angle X-Ray Scattering* Structural information of both particles and particle–particle interactions is contained in the SAXS scattering pattern. It can be difficult to interpret SAXS data, especially for complex systems. For a monodisperse spherical system, the scattering intensity is related to the form factor by the following equation:

$$I(q) = \Delta\rho^2 N_\mathrm{p} V_\mathrm{p}^2 P(q)$$

where $I(q)$ is the scattering intensity, $P(q)$ the form factor, $q$ the scattering vector, $4\pi\sin(\theta/2)/\lambda$, $\Delta\rho$ the difference in the scattering length density between the solvent and the colloid, $N_\mathrm{p}$ the number of particles in a sample, and $V_\mathrm{p}$ is the volume of a particle.

Particle dimensions may be calculated by determining a good fit of the scattering pattern with established models or by using a Guinier plot to determine radius of gyration.

$$I(q) = \Delta\rho^2 N_p V_\mathrm{p}^2 \exp(-q^2 R^2/3)$$

where $I(q)$ is the intensity, $\Delta\rho$ the difference in the scattering length density between the solvent and the colloid, $N_\mathrm{p}$ the number of particles in a sample, $V_\mathrm{p}$ the volume of a particle, $R$ the radius of gyration, and $q$ is the scattering vector, $4\pi\sin(\theta/2)/\lambda$.

Plots may be constructed by plotting the natural log of intensity versus $q^2$, with a slope of $-R^2/3$. This is only valid for $q < 1/R$ (45).

***3.2.3 Neutron Scattering*** Neutrons are generally scattered by the nuclei of atoms, and the scattering is not dependent upon the atomic number. Atomics with close atomic numbers (including hydrogen) may be distinguished from each other. The basic scattering equations are similar to SAXS. Additional structural information may be gained by SANS by taking advantage of "contrast matching" out portions of the sample that are not being analyzed (e.g., the solvent) by using the correct ratio of $D_2O$ to $H_2O$.

***3.2.4 Ion Scattering*** Unlike the previous methods, ion scattering methods tend to be inherently destructive to a sample. Not only are sample layers etched away in the ion beam bombardment, but also ions can become imbedded within the sample. In addition, a full vacuum is usually required for sample analysis.

## 3.3 Separation

***3.3.1 Analytical Ultracentrifugation*** AUC can provide structural and conformational information about particles. Two main modes are used in AUC, sedimentation velocity and sedimentation equilibrium and they can be used sequentially to provide information about the particle and particle interactions in a particular system.

Sedimentation velocity experiments use high rotor speeds and detectors to determine the time course of sedimentation. Size, size distribution, and shape may be calculated with this method.

Sedimentation equilibrium experiments use lower rotor speeds and can probe interactions between particles and other moieties in the system such as binding information, strength of binding, and self-association as each non-interacting species is separated into a unique boundary. The size of the complexes may also be determined. As the chemical equilibrium of the system is not perturbed with this method, AUC can be an ideal technique for looking at formulated products (provided that they are in a form amenable to this type of procedure).

Three forces will act on the suspended particle when subject to a gravitational field, the gravitational force, the buoyant force, and the frictional force. These forces come into balance and provide the following equation:

$$\frac{M(1-\bar{\nu}\rho)}{Nf} = \frac{u}{\omega^2 r}$$

where $M$ is the molar weight of the solute (in g/mol), $N$ the Avogadro's number, $\nu$ the partial specific volume of thee particle (in mL), $\rho$ the density of the solvent (g/mL), $\omega$ is the angular velocity (in radians per second), $r$ the distance of the particle from the axis of rotation, $f$ is the frictional coefficient, $u$ the particle velocity, and $u/\omega 2r$ is the sedimentation coefficient, which depends on the particle properties.

## 3.4 Miscellaneous Methods

***3.4.1 Acoustic Attenuation Spectroscopy*** As no optics are involved, AAS can be used to analyze particle size and particle size distribution in dilute to opaque samples. Thus, opaque and/or concentrated particle suspension that cannot be dried and analyzed may be characterized using this technique.

***3.4.2 Raman Spectroscopy*** As with XRD, reducing the crystallite size to nano-dimensions results in broadening the peaks of the Raman spectrum. In addition to peak broadening, the following effects may also occur: small downshifts in transverse optic mode wave numbers, decreases in the separation of longitudinal and transverse modes, and changes in band intensity. These effects occur after decreasing the crystallite size below 1 μm. Different models may be applied to calculate crystallite size from the Raman spectrum, which are beyond the scope of this chapter (46,47).

***3.4.3 Differential Mobility Analysis*** Not all pharmaceuticals are solvent or solid based. DMA is a traditional instrument for measuring aerosol particles. Particles are injected into a clean gas and exposed to an electric field. Separation of the particles

is based upon electrical mobility, which is based upon the size and charge of the particle. By varying the applied field, a size distribution of the particles may be obtained.

## 3.5 Surface Methods

Zeta potential measurements are frequently used to evaluate a sample's surface charge and stability. The particle surface itself is not measured. A charged particle's surface is surrounded by a layer of ions called the "fixed layer." This layer is, in turn, surrounded by a more diffuse region comprised of oppositely charged counter ions. This area is termed the "diffuse double layer" and the entire region is electrically neutral. During a zeta potential measurement, a voltage is applied across the solution, and particles are attracted to the electrode of opposite polarity. The fixed layer goes along for the ride with the particle, as does some of the diffuse double layer. The boundary in the diffuse double layer between going with the particle and staying put is what is measured. Stability in a colloidal system occurs when columbic repulsions between the particles is greater than the Van der Waals forces. Typically a zeta potential of ±30 will result in a stable system and is measured by electrophoretic mobility by the Henry equation:

$$U_{\mathrm{E}} = 2\varepsilon\zeta f(\kappa a)/3\eta$$

where $U_{\mathrm{E}}$ is the electrophoretic mobility, $\varepsilon$ the dielectric constant, $\zeta$ the zeta potential, $\eta$ the viscosity, and $f(\kappa a)$ is the Henry's function, with "$1/\kappa$" the "thickness of the electric double layer (Debye length), and "$a$" the particle radius. In polar media, the maximum value of Henry's function is approximated as 1.5 (Smoluchowski approximation). The minimum value is 1 for non-polar media (Hückel approximation).

Usually, measurement systems are limited to currents lower than 200 μA (to avoid electrolytic reactions) and conductivities of 10 μS/cm (ionic strengths of 0.1–100 mM).

***3.5.1 Brunauer, Emmett, Teller (48)*** This method calculates the total and external surface area of a material based upon gas (usually nitrogen) adsorption. The measurements are based upon BET theory:

$$\frac{P}{V(P^{\mathrm{o}}-P)} = \frac{1}{V_{\mathrm{m}}c} + \frac{(c-1)}{V_{\mathrm{m}}c} \times \frac{P}{P^{\mathrm{o}}}$$

where $V$ is the volume of gas adsorbed at pressure $P$, $P^{\mathrm{o}}$ the saturated pressure of adsorbing gas at a designated temperature, $c$ the BET constant ($\exp[(H_{\mathrm{a}} - H_{\mathrm{l}})/\mathrm{RT}]$) with $H_{\mathrm{a}}$ the enthalpy of adsorption of the gas on the solid and $H_{\mathrm{l}}$ the heat produced on forming the second and succeeding layers, $T$ is temperature and $R$ is the gas constant, and $V_{\mathrm{m}}$ is the volume of gas adsorbed to form a monolayer on a surface.

The surface area of the material may be determined by plotting $P/V(P^{\mathrm{o}} - P)$ versus $P/P^{\mathrm{o}}$ (Intercept $= 1/V_{\mathrm{m}}c$, Slope $= (c-1)/V_{\mathrm{m}}c$), $V_{\mathrm{m}} = 1/(\text{slope} + \text{intercept})$.

$$\text{The number of molecules adsorbed onto the surface is} = V_m N / V_R$$

where $N$ is the Avogadro's number and $V_R$ is the molar volume of and ideal gas.

Finally, the surface area is the number of molecules multiplied by the area per molecule (0.162 $nm^2$ for $N_2$).

## 3.6 Pharmaceutical Specific Considerations

In some cases, it is necessary to distinguish between primary particles, aggregates, and agglomerates in a nano-therapeutic. In addition, if the particles are changing form during the life time of the material, the different entities will need to be characterized. In general, techniques such as EM and SPM can often identify the different moieties for visual analysis of the material. Scattering and separation methods, while able to size the different size populations, cannot always identify which specific type of moiety is being sized. Methods such as DLS, however, are able to evaluate how different conditions (time, temperature, pH, solvent, etc.) affect the aggregation/agglomerate on particles using real-time time course experiments.

***3.6.1 In vitro Considerations*** In many cases, small molecule techniques used to determine characteristics such as dissolution, bioavailability, and so on, may be sufficient to analyze nano-materials. However, nanoparticle interference has been observed for some assays, especially chemical-based toxicity assays (51). As this inference can produce strong false-positive or false-negative results, it is important to run the appropriate controls with each nanoparticle and assay to determine how, if at all, the nanoparticles are interfering with a particular test. Along with nanoparticle controls, effects of any buffers or chemicals upon the nano-pharmaceutical should be noted (e.g., strong agglomeration in a buffer).

***3.6.2 In vivo Considerations*** After adequate characterization of the nano-material, it will be necessary to characterize how it behaves in animal models. Nano-materials are large enough that they can be directly observed in tissues through various methods described earlier. This visualization may allow for a more direct determination of therapeutic localization (in contrast to small molecules where methods such as histopathology may provide indirect information about localization of the therapeutic). In the case of non-carbon based nano-systems, the identification of the materials may be straightforward. Carbon based materials present more challenges, although they too can be positively identified.

As with small molecule therapeutics, radio labeling can provide accurate localization of materials. In addition, if the material is not carbon based (e.g., a metal oxide) bulk measurement techniques, such as ICP-MS, XRF, or NAA, can provide tissue concentrations in the ppb range. If a nano-material incorporates imaging moieties, then imaging techniques such as MRI may be employed. Such versatility in localization and imaging is an advantage over radiolabeling. However, it can often

be difficult, especially with complex nano-materials, to determine the state of the particle once inside the tissue (e.g., are ligands still attached, etc.).

In terms of locating the particles within tissues, TEM is often the gold standard. When coupled with one of the compositional attachments such as EDS or EELS, particles may be accurately identified not only in tissues but also in sub-cellular locations. Depending on the size and concentration of the materials, other EM methods could be used. If the material is fluorescently labeled, or has a substantially different RI than the surrounding tissue, OM methods can also be used to locate particles. Both optical and SEM methods can be made environmental, but additional staining procedures may still be needed to enhance contrast.

For TEM procedures, tissues are usually fixed, embedded, stained, and sectioned prior to analysis (24). Cryo-techniques may also be used to avoid interactions with staining dyes or fixatives and the nano-materials. As most TEMs require high vacuum and thin samples, sample preparation is more involved. Introducing stains and fixative procedures may also introduce artifacts, and it is extremely important to ensure that these artifacts are not mistaken for the nano-material as they are often similar in size.

In a typical fixation procedure, tissues are first fixed with an aldehyde (glutaraldehyde or formaldehyde), post-fixed with osmium tetroxide, dehydrated through ethanol grades, infiltrated/embedded with resin, sectioned and stained (uranyl acetate and lead citrate are common) (24). As some stains or fixatives may interact with the nanoparticles, the staining protocol should be planned in its entirety prior to working with the tissues. This planning will prevent unfortunate accidents such as a fixative dissolving the nanoparticles.

## 4 METHODS

In all cases, proper sample handling and preparation should be observed for characterization procedures. In all cases, it is imperative to obtain a representative sample of the therapeutic, and methods are available to help with sample handling (25). Nano-materials can be formulated into a wide range of materials, and these materials may lend themselves to certain analytical methods. Table 4 highlights techniques that may be used for the characterization of different materials.

### 4.1 Deciding on Appropriate Instrumentation

When beginning the characterization procedure, several factors need to be taken into account including the material to be tested, the conditions desired for the measurement, and the type of data needed for the characterization. Some of these factors are more limiting than others and should be considered earlier in the decision process. Figure 4 shows an example of a decision tree used to determine appropriate nano-methods for sizing a powder sample under environmental conditions.

Many techniques are complementary to each other, while others can verify information from another method. For this reason, it is recommended that more

a) If a general class, rather than a specific method is listed, then all sub-instruments and attachments in that class may be used.

than one technique initially be used to characterize nano-materials. Once a technique has been established and validated, then it may become acceptable for one method to be used, but initially, every reasonable effort should be made to test a material with multiple nano-methods.

## 4.2 Tools for Specific Materials

***4.2.1 Powders*** If the particle must remain in the powder state for analysis, most of the microscopy methods, including ones requiring a high vacuum and their various attachments can be utilized. The range of instrumentation increases if the particles are able to be suspended in a liquid medium.

***4.2.2 Liquid Dispersions*** Liquid dispersions are a very versatile class of materials to analyze. Not only are many of the characterization techniques solvent based but also if the material may be cryo-frozen or dried, then most of the characterization techniques are available for use.

***FIGURE 4*** *Hypothetical example of a decision tree used to determine appropriate nano-methods. In this example, the goal is to obtain sizing information for powders under environmental conditions.*

***4.2.3 Aerosols*** If formulations are delivered in aerosol form ATOMS, PHA-UCPC, or DMA would be appropriate instruments to use for characterization. If the final material is placed onto sample grids, then techniques used to analyze powders may also be applied for both sizing and compositional information.

***4.2.4 Gel/Paste/Emulsion/Complex Formulation*** Although analytical nano-methods should be considered for each material, complex formulations require additional thought. If the formulation is viscous and will be fundamentally changed by dilution (such as many creams or lotions) then many of the liquid based methods will be unavailable. On the other hand, if drying the material will change the formulation and/or the nano-material and its interaction with the formulation, then all methods requiring a vacuum will be inappropriate as well. In some cases, only environmental techniques will be possible, and although this will limit the type and resolution of the data obtained, many environmental techniques are now providing data at increasingly high resolution. If the material may be dried or diluted, then solid and liquid dispersion techniques can be used.

***4.2.5 Solid Formulations*** In some cases, the nano-material will be embedded into another material (such as nanocomposites for tissue scaffolds or drug eluting stents). In these cases, the entire material may need to be evaluated and, as a result, many solvent-based techniques will be eliminated. In order to access some instruments, the material may need to be sectioned (TEM) or damaged (FIB, SIMS) for analysis.

### 4.3 Non-Perturbing/Environmental Methods

In some cases, the material must be tested in environmental conditions. This requirement is especially true if modifications to the sample during preparation or analysis (e.g., drying or dilution) is expected to change the nano-content or how it interacts with the rest of a formulation. Examples would include some nano-emulsions, or topical products such as creams that contain nano-materials. In such cases, the choice of instrumentation may be severely limited. Depending on the material tested, standard testing procedures may not be possible. If the material is analyzed with a destructive technique, the additional changes to the material should be noted. Although some instruments may be environmental for certain samples (e.g., liquid dispersions and light scattering techniques), truly environmental methods should be able to handle all materials.

## 5 CONCLUSIONS

Nano-therapeutics have been often viewed similarly to small molecule therapeutics. However, differences may arise during some of the characterization steps where nano-materials may interfere with common assays and tests, or non-traditional analytical instrumentation may be needed in order to fully characterize the material. In order to ensure that the material is correctly and completely identified, several analytical methods may be initially needed to evaluate the material. Finally, the final formulation should be tested to characterize any changes to the formulation or nano-material during the manufacturing process.

## 1 INTRODUCTION: WHY DESIGN AND RUN EXPERIMENTS IN THE PHARMACEUTICAL INDUSTRY?

While some discoveries and revolutionary improvements have come about by ad hoc methods, tinkering, or even accidents, a disciplined approach to discovering new products, developing them into salable form, and improving the processes by which they are produced is more efficient and effective. With such a disciplined approach, the quality of products and processes are embedded in their designs. This "quality by design" may be achieved through effective use of experimental methods. In this brief overview, we discuss many different methods that may be used to explore how changes to inputs (factors, explanatory or independent variables) affect outputs (responses or dependent variables). As opposed to passively observing changes and reacting to them, we describe methods in which we purposively change the values of factors in order to study their impact on one or more responses.

When attempting to optimize a product, process, or system, researchers often vary one factor at a time (OFAT), holding others fixed, in order to assess the impact of the factor on the response or responses. Design of experiments (DoE) methods allow

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing,*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

researchers to vary multiple factors at a time in a systematic fashion, in order to obtain more information for the same amount of resources. DoE is by no means new, having been applied in the agricultural sciences since the early 20th century. Varying amounts and types of fertilizers, as well as irrigation levels, allow one to study the impact of these factors on crop yield. Of course, there are many differences between performing experiments in a field and performing them in a laboratory or a manufacturing setting. For example, agricultural experiments may require months to obtain data while laboratory results may be available in minutes or hours. Agricultural experiments are often victims of much variation between fields, clouding differences between fertilizer and irrigation treatments. In a chemical experiment, labortory conditions and measurement error may be the main sources of background noise in the data.

Yet, many industries have incorporated DoE as an important tool for product/process improvement. Many of these firms, General Electric and Ford Motor Company, for example, use DoE as part of a "Six Sigma" effort for process improvement and product development. The types of experiments and their analyses that are applicable in the auto industry may differ somewhat from those in agriculture, which may differ from those in the pharmaceutical industry. We will focus on those of main interest in pharmaceuticals.

So where are these techniques used in the pharmaceutical industry? According to Laird (1), "Combinatorial chemistry and high-throughput screening have dramatically influenced the way compound discovery is carried out. . . ." He later states ". . . automated techniques lend themselves to a combination with statistically designed approaches (design of experiments, DOE) such as factorial designs, simplex optimisation, and response surface designs." Gooding et al. (2) applied DoE in conjunction with an automated synthesizer to optimize the synthesis of amides. Owen et al. (3) provide a step-by-step description of a case study involving the desilylation of a silyl ether to produce alcohol, a key step in the synthesis of a trinem antibiotic. Lutz et al. (4) descibe the use of DoE in high-thoughput screening. Tye (5) provides encouragement for DoE usage in the pharmaceutical industry and cites many example applications. Throughout this chapter, we will introduce other examples.

The rest of the chapter is organized as follows. The next section introduces basic experiments and their analyses where only one or two factors are studied. (We assume the reader has some familiarity with multiple linear regression and common statistical distributions including the normal and $t$. For more details on regression, see Kutner et al. (6).) Section 3 introduces factorial experiments and experiments useful for screening. Screening designs are useful for separating a large number of factors into those that are the most important and those that have less of an impact on the response. They are very useful when there are numerous variables resulting in many combinations to be tested as in, for example, drug discovery. Having reduced the number of factors of interest, in Section 4 we then discuss experiments that are useful for optimization. In these experimental designs such as response surface and simplex designs, a small number of factors are studied in order to find a combination of settings that will provide the most desirable response or responses.

Our discussion will focus on the design and analysis of an experiment once the factors have been identified. Due to page limitations, we will not discuss important issues such as what factors to include, how to determine the levels (settings) of a quantitative factor, and others. For a detailed discussion of these and other experimental matters, see Coleman and Montgomery (7).

## 2 BASIC EXPERIMENTAL DESIGNS AND ANALYSES

### 2.1 Single Factor Studies

Suppose all process variables are set to their nominal values in a chemical process and two batches of the same chemical are produced. If the yield of each is measured, will these yields be identical? Generally, the answer is no. If there is enough precision in the measuring system, the yields will not be identical, differing due to small changes in the process variables that were presumably fixed and other variables that were not controlled (ambient humidity and temperature for example). We can describe this with a statistical model as follows: Let $y_i$ be the response (yield in our example) for batch $i$. Then if we process multiple batches at the same settings of the process variables, we expect the yields to vary somewhat randomly around some average, say $\beta_0$. The variation around this average is a result of "noise" from minor deviations from nominal in the process variables and variation in other uncontrolled and possibly unobserved variables. This leads to the model in equation (1):

$$y_i = \beta_0 + \varepsilon_i \tag{1}$$

Here, $\beta_0$ is the mean yield and $\varepsilon_i$ is a random variable representing all of the noise or *error*. We assume that $\varepsilon_i$ has expected value 0 and variance $\sigma^2$. In order to perform statistical inference, we will also assume the $\varepsilon_i$ follows a normal distribution, or more succinctly, $\varepsilon_i \sim N(0, \sigma^2)$.

Now suppose the reaction temperature was 225°C for the first batch and was changed to 250°C for the second batch. We need to adapt model (1) to include the value and effect of reaction temperature. Let $x_{i1}$ be the reaction temperature for batch $i$ ($x_{11} = 225$ and $x_{21} = 250$). Now we may use the model in equation (2) below.

$$y_i = \beta_0 + \beta_1 x_{i1} + \varepsilon_i \tag{2}$$

Viewing this as a regression model, $\beta_1$ is the slope, which quantifies how much the response changes, on average, for a unit change in the factor. Note that if $\beta_1 = 0$, then the mean yield is the same regardless of reaction temperature and (2) reduces to (1). In this case, we refer to reaction temperature as being inactive. For $\beta_1 \neq 0$, reaction temperature is considered to be active, as increasing the temperature increases (decreases) the yield for $\beta_1 > 0 (\beta_1 < 0)$.

However, the parameters $\beta_0$, $\beta_1$, and $\sigma^2$ are unknown and must be estimated from the data from the experiment. If we only observe two batches (one at each of two temperatures), then we can estimate $\beta_0$ and $\beta_1$ but cannot estimate $\sigma^2$. Without knowing (or being able to estimate) $\sigma^2$, we cannot perform statistical inference to

decide if $\beta_1 \neq 0$ or not. So, in a simple experiment such as this, it is desirable to replicate the experiment by observing more than one batch at each level of the factor. The order that the experimental units are processed should be randomized. For example, if we were to observe three batches at each temperature, the order that the six batches are processed should be determined randomly.

## 2.2 Two-Factor Studies

***2.2.1 Unreplicated Two-Factor Studies*** In most designed experiments, multiple factors are systematically varied in order to assess their effect on one or more responses. Extending our chemical processing example, suppose we study catalyst amount as a factor in addition to reaction temperature. Temperature is studied at two levels as before (225 and 250) and catalyst at levels of "low" and "high." When each factor has only two levels, it is convenient to label them $-1$ and $+1$, or simply $-$ and $+$. Note that there are four temperature–catalyst combinations or *treatments*: (225, low), (250, low), (225, high), and (250, high) or $(-, -)$, $(+, -)$, $(-, +)$, and $(+, +)$. A single batch was produced for each treatment. In an unreplicated experiment such as this, each treatment is only observed once. Table 1 shows the levels of temperature ($x_1$) and catalyst ($x_2$) as well as the yield ($y$). We will discuss the other columns shortly.

The four responses are $y_{--} = 73$, $y_{+-} = 80$, $y_{-+} = 77$, and $y_{++} = 77$. Based on these four observations, can we quantify the effect of temperature ($x_1$) on the response? A simple and effective way to do so is to compare the average response at high temperature ($x_1 = 1$) to the average response at low temperature ($x_1 = -1$). The quantities we need are $(y_{+-} + y_{++})/2 = (80+77)/2 = 78.5$ and $(y_{--} + y_{-+})/2 = (73+77)/2 = 75$. So our estimate of the effect of temperature is $78.5-75 = 3.5$, meaning we estimate that the yield is 3.5% greater at the higher temperature. With our $+1$ and $-1$ coding, the "high" level of a factor is two units above the "low" level of the factor. So a two-unit increase in $x_1$ is associated with an increase of 3.5 in $y$, or equivalently, a one unit increase in $x_1$ is associated with an increase of 1.75 in $y$. This, of course, is the estimated slope of $x_1$. In a similar manner, the effect of catalyst is $(y_{-+} + y_{++})/2 - (y_{--} + y_{+-})/2 = (77+77)/2 - (73+80)/2 = 0.5$ and the estimated slope is 0.25.

***2.2.2 Two-Factor Model*** For an experiment with two factors ($x_1$ and $x_2$), our model may be written as

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_{12} x_{i1} x_{i2} + \varepsilon_i, \qquad \varepsilon_i \sim N(0, \sigma^2) \tag{3}$$

**TABLE 1 Unreplicated Two-Factor Example**

| $x_0$ | $x_1$ | $x_2$ | $x_1x_2$ | $y$ |
|---|---|---|---|---|
| 1 | −1 | −1 | 1 | 73 |
| 1 | 1 | −1 | −1 | 80 |
| 1 | −1 | 1 | −1 | 77 |
| 1 | 1 | 1 | 1 | 77 |

$\beta_0$ is a constant representing the mean response and may be estimated by $\hat{\beta}_0 = (y_{--} + y_{+-} + y_{-+} + y_{++})/4 = (73 + 80 + 77 + 77)/4 = 76.75$. $\beta_1$ and $\beta_2$ are the slopes quantifying the increase in the response for unit changes in factors $x_1$ and $x_2$, respectively. Above we estimated these quantities with $\hat{\beta}_1 = 1.75$ and $\hat{\beta}_2 = 0.25$.

The product $x_{i1}x_{i2}$ (which, notationally, could be labeled $x_{i3}$) represents the interaction between factors $x_1$ and $x_2$, and $\beta_{12}$ represents the magnitude of this interaction. Two factors are said to interact if the effect of one factor depends on the level of the other. Note that if we multiply the elements of $x_1$ by those of $x_2$, we get $x_1x_2 = (+, -, -, +)'$. So as we did for the effects of $x_1$ and $x_2$, we estimate the interaction effect as $(y_{--} + y_{++})/2 - (y_{+-} + y_{-+})/2 = (73 + 77)/2 - (80 + 77)/2 = -3.5$ and $\hat{\beta}_{12} = -1.75$. One way to interpret this quantity is the effect of $x_1$ when $x_2 = +1$ minus the effect of $x_1$ when $x_2 = -1$. So here, the effect of increasing temperature by one unit at the high level of catalyst is 1.75 less than at the low level of catalyst. Putting this together we can get a model for predicting the yield, $\hat{y}_i = 76.75 + 1.75x_{i1} + 0.25x_{i2} - 1.75x_{i1}x_{i2}$. However, without replication we cannot estimate $\sigma^2$ and, therefore, cannot test hypotheses. In other words, we cannot judge whether any of the estimated coefficients are significantly different from 0.

Eqs. (1–3) may all be written in matrix form as

$$\mathbf{y} = \mathbf{X}\beta + \varepsilon, \qquad \mathrm{Var}(\varepsilon) = \sigma^2\mathbf{I} \tag{4}$$

The $n \times p$ matrix $\mathbf{X}$ consists of columns $\mathbf{x}_0, \ldots, \mathbf{x}_{p-1}$. $\mathbf{x}_0$ is a column of $n$ 1s representing the intercept. $\beta = (\beta_0, \ldots, \beta_{p-1})$ is a $p$-dimensional vector of unknown parameters that need to be estimated. To estimate these $p$ quantities, we need $p$ degrees of freedom and thus, at least, $p$ observations. With a total of $n$ observations, we have $n-p$ degrees of freedom left to estimate $\sigma^2$. The first four columns of Table 1 show the $\mathbf{X}$ matrix for our unreplicated example. Note that here $n = p = 4$, so $n-p = 0$, and we do not have any degrees of freedom to estimate $\sigma^2$ as previously stated.

Using this matrix notation, formulas can be given for many quantities of interest. More details can be found in any regression text (see, for example, Kutner et al. (6)). We list the ones that will be most useful for our purposes. As statistical software is readily available for this, we will then focus on interpreting the output from software.

The ordinary least squares estimator of $\beta$ is

$$\hat{\beta} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} \tag{5}$$

and the variance–covariance matrix of $\hat{\beta}$ is

$$\mathrm{Var}(\hat{\beta}) = \mathbf{V} = (\mathbf{X}'\mathbf{X})^{-1}\sigma^2 \tag{6}$$

The fitted values of the response are

$$\hat{\mathbf{y}} = \mathbf{X}\hat{\beta} = \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} \tag{7}$$

and we can estimate $\sigma^2$ with

$$s^2 = (\mathbf{y}-\hat{\mathbf{y}})'(\mathbf{y}-\hat{\mathbf{y}})/(n-p) \tag{8}$$

Putting it all together, we can estimate $\mathbf{V}$ with

$$\widehat{\mathrm{Var}(\hat{\beta})} = \hat{\mathbf{V}} = (\mathbf{X}'\mathbf{X}')^{-1}s^2 \tag{9}$$

The $j$th diagonal term of $\hat{\mathbf{V}}$, denoted $v_{jj}, j = 0, \ldots, p-1$, is the estimate of $\mathrm{Var}(\hat{\beta}_j)$, and the square root of this quantity is known as the standard error of $\hat{\beta}_j$, or $\sqrt{v_{jj}} = \mathrm{s.e.}(\hat{\beta}_j)$. We will see $\sqrt{v_{jj}} = \mathrm{s.e.}(\hat{\beta}_j)$ in much of our computer output.

***2.2.3 Replicated Two-Factor Studies*** Once again extending our example, now suppose that 12 batches were processed as follows. Each of the four treatments were applied to three different batches (resulting in $r = 3$ replications) with the order of experimentation randomized. In Table 2, column $i$ shows the order of experimentation, or batch number, and the $x_1$ and $x_2$ columns define the experimental design. Collectively, the columns $x_0$, $x_1$, $x_2$, and $x_1x_2$ form the $\mathbf{X}$ matrix. Note we have $n-p = 12-4 = 8$, so we have eight degrees of freedom to estimate $\sigma^2$ using Eq. (8). We (or more likely a software package) can then test to see if the coefficients differ significantly from 0.

Running least squares regression in any statistics package will result in output similar to that given in the Table 3. The column labled "estimate" gives the estimated slopes or coefficients ($\hat{\beta}_j$s). For our $-1$ and $+1$ coding, the slope is half of the difference between the mean response at the $+$ and $-$ levels of a column. From Table 2 we can calculate the mean response for each of the four unique treatments, namely, $\bar{y}_{--} = 69$, $\bar{y}_{+-} = 79$, $\bar{y}_{-+} = 74$, and $\bar{y}_{++} = 81$, where the first subscript refers to the level of $x_1$ and the second to that of $x_2$. We may then perform calculations as we did in the unreplicated case using means in place of the individual observations. So $\hat{\beta}_1$ is $\frac{1}{2}\left(\frac{79+81}{2} - \frac{69+74}{2}\right) = 4.25$, and the mean yield is $2 \times 4.25 = 8.5\%$ greater at

**TABLE 2 Replicated Two-Factor Example**

| $i$ | $x_0$ | $x_1$ | $x_2$ | $x_1x_2$ | Yield (y) |

| 10 | + | + | + | + | 82 |
| 11 | + | + | + | + | 84 |
| 12 | + | + | − | − | 76 |

**TABLE 3 Two-Factor Experiment Regression Output**

| | Estimate | Std. Error | *t*-value | Pr(> \|t\|) |
|---|---|---|---|---|
| (Intercept) | 75.750 | 1.010 | 74.973 | 1.12e-12 |
| $x_1$ | 4.250 | 1.010 | 4.206 | 0.00297 |
| $x_2$ | 1.750 | 1.010 | 1.732 | 0.12150 |
| $x_1x_2$ | −0.750 | 1.010 | −0.742 | 0.47913 |

the higher temperature than at the low. The other columns in the display are used to perform inference about the coefficients. Recall that a factor (or interaction) is active if its slope (coefficient) differs from 0. The output allows us to perform the hypothesis test $H_0 : \beta_j = 0$, $H_1 : \beta_j \neq 0$. Under the assumptions of our model, $t_j = \text{estimate}/\text{std. error} = \hat{\beta}_j/\text{s.e.}(\hat{\beta}_j)$, called a test statistic, follows a $t$ distribution with $n-p$ degrees of freedom.

The $p$-value for a hypothesis test is the probability of observing the test statistic we did ($t_j$), or something more in favor of $H_1$, assuming that $H_0$ is true. The larger the $t_j$-value is, the smaller the $p$-value is and the more evidence there is against $H_0$. So for us, a small $p$-value (0.05 is often used to define small) suggests that $H_1 : \beta_j \neq 0$ is true, i.e., that the factor has an effect on the mean response. A common cutoff value for deciding to reject $H_0$ in favor of $H_1$ is 0.05.

From Table 3 we can see the intercept and $\beta_1$ (the $x_1$ term) differ significantly from 0. So we can conclude that the higher reaction temperature leads to a higher yield, but we do not have sufficient evidence to state that the yield is affected by changing the amount of catalyst. It is important to note that this does not mean that the amount of catalyst has no effect on the yield. It does mean that based on the levels studied for this factor, and the amount of data collected, we do not have enough evidence to see a statistically significant difference from 0 in $\beta_2$.

Similarly, the interaction between temperature and catalyst is not significant. The slope for the interaction is $-0.75$ equivalent to the interaction effect being $-1.50$. The interaction effect is the difference in the temperature effect at the high level of catalyst minus the temperature effect at the low level of catalyst. If there is no dfference between these two temperature effects, then the temperature effect does not depend on the catalyst level, and there is no interaction. This effect is actually $(1/2) \times [(81-74)-(79-69)] = -1.5$.

Figure 1, known as an interaction plot, shows the effect of temperature at the low level of catalyst separately from the effect of temperature at the high level of catalyst. Theoretically, the two lines in the plot will be parallel if there is no interaction. Substantial departures from parallelism indicate an interaction between the factors. We can see that in this case, the lines are roughly parallel, agreeing with our previous conclusion of no interaction.

## 2.3 Multi-Factor Studies

The example just discussed was quite simple in that only two factors were studied, each with two levels. Increasing the number of factors or the number of levels of factors increases the number of treatments. Continuing the chemical example,

***FIGURE 1*** *Interaction plot – temperature vs. catalyst.*

suppose three temperatures, two catalyst amounts, and four reaction times were to be studied. If all combinations are included in the experiment, there will be $3 \times 2 \times 4 = 24$ unique treatments requiring 24 batches even without any replication. When all possible treatments are studied as just discussed, we have a *factorial design*.

The number of factors to include and the number of levels of each depends on the goal of the study. There may be many goals when performing an experiment including:

- sorting factors into those that affect the response (active) and those that do not appear to affect the response (inactive);
- assessing the magnitude of the effect of factors on the response;
- determining which factors interact and assessing the magnitude of such interactions;
- finding settings of the factors that produce desirable responses.

Often, a series of experiments are used, each with different goals. An initial study may be used to do screening, i.e., find the factors that appear to be the most important.

These screening experiments generally have several to many factors, but each is studied at only two or perhaps three levels. Then, after identifying a small number of key factors, additional experiments may be performed in order to better quantify the effect of each factor or to find optimal settings. In the next section we discuss screening designs and then introduce designs for optimization in the section thereafter.

## 3 DESIGNS FOR SCREENING

Two factors at two levels each leads to $2 \times 2 = 2^2 = 4$ treatments. If each factor had three levels, we would have $3^2 = 9$ treatments, while three factors each at three levels leads to $3^3 = 27$ treatments. So increasing the number of factors or the number of levels of the factors rapidly increases the number of treatments. If the intent of the experiment is to separate the wheat from the chaff (find the important few factors among the less important many), then we may wish to study a relatively large number of factors, each with only two or three levels. In this section we will briefly study designs where all factors are studied at two levels. For more discussion of these designs and their analysis, see Box et al. (8), Wu and Hamada (9), and Montgomery (10).

### 3.1 Factorial Designs

Factorial designs consist of all combinations of factors; i.e., each treatment is observed. If each of $k$ factors has only two levels, then there are $2^k$ treatments. In Table 1 we have a $2^3$ tablet experiment from Khanvilkar et al. (11) in which three factors (A = hardness, B = viscosity, and C = polymer composition) were studied and multiple responses were measured. (To show another common notation, we have used A, B, and C instead of $x_1$, $x_2$, and $x_3$ to label the factors.) We focus on $t_{\text{lag}}$, which is the time (min) taken by the matrix tablet to get hydrated and achieve a state of quasi-equilibrium before erosion and the advance of solvent front through the matrix occur. The columns AB, AC, and BC represent interactions among two factors, and ABC represents the three-factor interaction (Table 4). (A three-factor interaction occurs when a two-factor interaction effect depends on the level of a third factor.)

**TABLE 4 Unreplicated $2^3$ Experiment from Khanvilkar et al. (11)**

| A | B | C | AB | AC | BC | ABC | $t_{\text{lag}}$ |
|---|---|---|---|---|---|---|---|
| − | − | − | + | + | + | − | 10.08 |
| + | − | − | − | − | + | + | 10.84 |
| − | + | − | − | + | − | + | 10.65 |
| + | + | − | + | − | − | − | 10.92 |
| − | − | + | + | − | − | + | 5.14 |
| + | − | + | − | + | − | − | 6.06 |
| − | + | + | − | − | + | − | 5.46 |
| + | + | + | + | + | + | + | 5.65 |

**TABLE 5 Output from Unreplicated $2^3$ Experiment from Khanvilkar et al. (11)**

| | Estimate | Std. Error | *t*-value | Pr(> \|*t*\|) |
|---|---|---|---|---|
| (Intercept) | 8.1000 | 0.0300 | 270.000 | 0.00236 |
| A | 0.2675 | 0.0300 | 8.917 | 0.07110 |
| B | 0.0700 | 0.0300 | 2.333 | 0.25776 |
| C | −2.5225 | 0.0300 | −84.083 | 0.00757 |
| AB | −0.1525 | 0.0300 | −5.083 | 0.12366 |
| AC | 0.0100 | 0.0300 | 0.333 | 0.79517 |
| BC | −0.0925 | 0.0300 | −3.083 | 0.19966 |

Note that in this experiment, only one observation is recorded for each treatment. Recall that this is known as an *unreplicated design*. The model may be written as

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3} + \beta_{12} x_{i1} x_{i2} + \beta_{13} x_{i1} x_{i3} + \beta_{23} x_{i2} x_{i3} +$$

$$\beta_{123} x_{i1} x_{i2} x_{i3} + \varepsilon_i, \quad \varepsilon_i \sim N(0, \sigma^2)$$

There are eight observations ($n = 8$) and eight $\beta$s ($p = 8$), each requiring one degree of freedom for estimation. Therefore, all degrees of freedom are used for parameter estimation ($n-p = 0$). In this case, $\hat{y}_i = y_i$ and $s^2 = 0$, so we cannot estimate $\sigma^2$ and cannot perform hypothesis tests.

One way to tackle this issue, the one used in Khanvilkar et al., is to assume one or more of the higher order interactions are inactive and leave them out of the model. Doing so pools that term or terms into error, providing at least one degree of freedom for testing. Khanvilkar et al. assumed the three-factor interaction was inactive ($\beta_{123} = 0$) and performed regression resulting in the output in Table 5. Clearly, factor C is significant, and no other terms are with the possible exception of A.

An alternative analysis method is to use the fact that if no effects are active, the estimates (ignoring the intercept) all follow a common normal distribution with mean 0 and unknown but constant variance. As such, they should behave as a random sample from a common normal distribution. Active effects have greater expected absolute values and should stick out from the noise of the inactive effects. Daniel (12) suggested using a half-normal plot of the effects or regression coefficients. Those that deviate substantially above a linear pattern emanating from 0 through the first few points are deemed to be active. Figure 2 shows a half-normal plot of the seven estimates from the tablet example. $\hat{\beta}_C$ clearly deviates from the roughly linear pattern of the others. An advantage of this approach is that all effects of interest can be assessed. A disadvantage is that it assumes effect sparcity, that only a few of the effects are actually active, and that the rest are trivial.

## 3.2 Fractional Factorial Designs

The previous example was an unreplicated $2^3$ design. By not replicating, experimental resources were saved. However, situations occur where resources are quite limited and even one observation for every treatment combination is not feasible. We saw that

***FIGURE 2*** *Half-normal plot – Khanvilkar et al., unreplicated $2^3$ with response $= t_{lag}$.*

from an analysis perspective, we can assume one or more effects are inactive and essentially use these to form an error term. But if we are willing to entertain the idea that some effects are inactive, then we may not need to observe all treatments. Consider a study reported by Menon et al. (13). Five factors (percent povidone ($P$), liquid/dry binder addition for povidone ($B$), atomization pressure ($A$), spray rate ($S$), and inlet air temperature ($I$)) were studied with responses of $y_1 =$ particle size (microns) and $y_2 =$ crushing strength (kP).

Suppose only the first four factors were to be studied in a $2^4$ design. Then once again using the $+1, -1$ coding, the design is displayed in columns $1-5$ in Table 6. Columns 5–15 represent the six two-factor interactions, the four three-factor interactions, and the four-factor interaction for these factors. If we want to study a fifth factor without additional runs, we assign the fifth factor to one of these columns, equating it with that effect. Column 15 is the PBA$S$ interaction, and we see that $I$ has been assigned to that column. So now column 15 represents a pair of effects, PBA$S$ and $I$. If we multiply columns 1 and 15 ($P$ and $I$) together, we get column 14 ($PI$), which is also BA$S$. In other words, PI $=$ BA$S$. Each column represents a pair of effects resulting in the pattern shown in Table 7. The effects in each pair are said to be confounded.

| 16 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 478.00 | 8.61 |

**TABLE 7 Confounding Pattern for the $2^{5-1}$ Example**

| Intercept = PBASI | PS = BAI |
|---|---|
| P = BASI | PI = BAS |
| B = PASI | BA = PSI |
| A = PBSI | BS = PAI |
| S = PBAI | BI = PAS |
| I = PBAS | AS = PBI |
| PB = ASI | AI = BAS |
| PA = BSI | SI = PBA |

So in Table 6, each column represents a pair of effects, and we have labeled each column with its lower order effect from the pairings listed above. The coefficients associated with $\log_{10}(y_1)$ and $y_2$ are listed in Table 8. Figure 3 is a half-normal plot, based on the $\log_{10}$ of response $y_1$ = particle size. From this plot it is clear that $S$ has the largest impact on the response. However, Menon et al. used the procedure of Lenth (14) as adapted by Haaland and O'Connell (15). First, we calculate $s_0 = 1.5 \times \text{median}(|\beta_j|)$. Next, a pseudo-standard error is calculated as $\text{PSE} = 1.5 \times \text{median}_{|\beta_j|<2.5s_0}|\beta_j|)$. Then each effect is tested by comparing $|\beta_j|$ to $t_{(1-\alpha/2,(p-1)/3)} \times \text{PSE}$. (Haaland and O'Connell suggest minor adjustments to these quantities.) For $\log_{10}(y_1)$, $s_0 = 0.05119085$, $\text{PSE} = 0.05011927$, $t_{(.975,15/3)} = 2.570582$, and the critical value is $t_{(.975,15/3)} \times \text{PSE} = 0.1288357$. Thus we see that $S$ is the only significant effect. (We note that Menon et al. showed a different (apparently incorrect) value for PSE and found many effects to be significant.)

Using the coefficients for $y_2$ = strength, Lenth's procedure results in PSE = 1.028438 and a critical value of 2.643683. Based on this procedure, none of the effects are significant. Half-normal plotting and Lenth's procedure are just two of many methods that have been developed to analyze unreplicated fractional factorial designs. See Hamada and Balakrishnan (16) for an extensive discussion of other methods that may be used to analyze unreplicated two-level experiments.

Of the $2^4$ treatments in the factorial design of this example, only $1/2 = 2^{-1}$ or $(2^{-1})(2^4) = 2^{4-1}$ were studied. This is a half-fraction of the full factorial design. In general, if only a $2^{-f}$ fraction of a $2^k$ factorial is run, the design is often called a $2^{k-f}$. Selection of the specific fraction to use is very important and is discussed in texts such as Montgomery (10).

## 3.3 Plackett and Burman Design

Plackett and Burman (17) provided a series of two-level fractional factorial designs for examining $n-1$ factors in $n$ runs, where $n$ is a multiple of 4 and $n \leq 100$. They omitted the case $n = 92$, which was later provided by Baumert et al. (18). When only main effects exist, these designs estimate all of them. Moreover, they are available for all run sizes that are a multiple of 4 (vs. a power of two as in a $2^{k-f}$ design). PB designs are thus extremely useful in screening situations. Note that the main effect of each factor can be evaluated by $\bar{y}_+ - \bar{y}_-$ as described in Section 2.2. Moreover, each column is orthogonal to all other columns. In other words, the inner product of any two columns is zero. Designs with such a property are called *orthogonal main-effect designs*.

*Construction of Plackett and Burman Designs*

A 12-run Plackett and Burman design can be obtained as follows:

1. Write down the set of signs $++-+++---+-$, provided by Plackett and Burman (17).

2. Permute the signs in 11 rows total, by taking the sign from the right hand side and moving it to the left hand side.
3. Add a 12th row of all minus signs.

For $n \leq 24$, all of the Plackett and Burman designs can be obtained by such a cyclic permutation. The signs for the first rows are:

$$
\begin{aligned}
n &= 8: \; + + + - + - - \\
n &= 12: \; + + - + + + - - - + - \\
n &= 16: \; + + + + - + - + + - - + - - - \\
n &= 20: \; + + - - + + + + - + - + - - - - + + - \\
n &= 24: \; + + + + + - + - + + - - + + - - + - + - - - -
\end{aligned}
$$

For $n$ a power of 2 (e.g., $n = 8$ and 16), we obtain a standard $2^{k-f}$ design. Note that Plackett and Burman designs can be viewed as a special class of orthogonal arrays (OAs). A complete list of OAs is given in Hedayat et al. (19) and can be found at the Web site http://www.research.att.com/~njas/oadir/.

## 3.4 Optimal Design

Recall from (4) that $\mathbf{X}$ represents the design matrix. From Eqs. (5)–(9) we see that $\mathbf{X}'\mathbf{X}$ plays an important role in inference. Specifically, an "optimal" design should be the one which minimizes $\mathrm{Var}(\hat{\beta})$ as in Eq. (6). In other words, one seeks the design whose $(\mathbf{X}'\mathbf{X})^{-1}$ matrix is minimized in some manner. Many design criteria have been proposed for choosing the design matrix $\mathbf{X}$ or for comparing design matrices. Essentially, most of them deal with the eigenvalues of the matrix $\mathbf{X}'\mathbf{X}$, $\lambda_1, \lambda_2, \ldots, \lambda_k$. The major alphabetical optimality criteria are as follows:

- *D-optimality*: maximize $\|\mathbf{X}'\mathbf{X}\| = \lambda_1 \times \lambda_2 \times \cdots \times \lambda_k$.
- *A-optimality*: minimize trace $(\mathbf{X}'\mathbf{X})^{-1} = \sum_{\mathrm{i}=1}^{\mathrm{k}} \lambda_{\mathrm{i}}^{-1}$.
- *E-optimality*: maximize the smallest eigenvalue of the $\mathbf{X}'\mathbf{X}$ matrix.
- *G-optimality*: minimize the maximum prediction variance over the operation region.
- *V-optimality*: minimize the average prediction variance over the operation region.

More (generalized) design optimalities can be found in Keifer (20), or more recently Pukelsheim (21). In essence, given the underlying model and the optimality criterion, any modern optimization technique can be used to generate an optimal design for the practitioner. However, the resulting design may not have desirable design properties, such as orthogonality, few levels in each factor, and symmetry, as in a $2^{k-f}$ design.

The problem of finding a D-optimal design has been very thoroughly explored mathematically; two early articles are by Hotelling (22) and by Mood (23). For two-level saturated D-optimal designs, the problem becomes finding an $n \times n$ matrix with

all its elements being either 1 or $-1$ such that its determinant is maximized. Such a "det-max" matrix problem has received a great deal of attention in the literature. Many of the resulting designs are available in software. If the underlying first-order design is believed to be true and if the optimality criterion is appropriate, these optimal designs can be very useful.

The practical value of saturated D-optimal designs, apart from Plackett and Burman (17) designs, is worthy of further investigation. First, these designs do not contain an equal number of high-level and low-level values. This can be quite disturbing to experimenters. The non-equal occurrence property implies that the factor is being partially confounded with the constant term (the column with all $+$'s), which is usually significantly different from zero. Second, unlike orthogonal designs, these designs lack similarity relationships among all the columns. For example, the correlations between every pair of columns are not necessarily the same. This raises questions about which factors to assign to which columns and whether it matters.

## 3.5 Supersaturated Designs

In order to obtain an unbiased estimate of the main effect of each factor, the number of experiments must exceed (or at least be equal to) the number of factors plus one (for estimating the grand average). When these two are equal, the design is called saturated and represents the minimum effort required to estimate all main effects. The standard advice given to users in such a screening process is to use the saturated design, which is "optimal" based upon certain theoretical optimality criteria. However, the non-significant effects are not of interest. Estimating all main effects may be wasteful if the goal is simply to detect those few active factors. If the number of active factors is indeed small, the use of a slightly biased estimate will still allow one to accomplish the identification of the active factors but significantly reduce the amount of experimental work. Developing such screening designs has long been a well-recognized problem, certainly since Satterthwaite (24).

When all factors can be reasonably arranged into several groups, group screening designs can be used (see, e.g., Reference 25). Only those factors in groups that are found to have large effects are studied further. The basic assumptions (such as the directions of possible effects are known), in fact, depend heavily upon the grouping scheme. While such methods may be appropriate in certain situations (e.g., blood tests), we are interested in systematic supersaturated designs for two-level factorial designs that can examine $k$ factors in $N < k + 1$ experiments in which no grouping scheme needs to be made.

***3.5.1 Supersaturated Designs Using Hadamard Matrices*** Lin (26) proposed a class of special supersaturated designs that can be easily constructed via half-fractions of Hadamard matrices. These designs can examine $k = N-2$ factors with $n = N/2$ runs, where $N$ is the order of the Hadamard matrix used. The Plackett and Burman (17) designs, which can be viewed as a special class of Hadamard matrices, are used to illustrate the basic construction method.

**TABLE 9 Plackett–Burman 12-Run Design**

| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 |
|---|---|---|---|---|---|---|---|---|---|---|
| + | + | − | + | + | + | − | − | − | + | − |
| + | − | + | + | + | − | − | − | + | − | + |
| − | + | + | + | − | − | − | + | − | + | + |
| + | + | + | − | − | − | + | − | + | + | − |
| + | + | − | − | − | + | − | + | + | − | + |
| + | − | − | − | + | − | + | + | − | + | + |
| − | − | − | + | − | + | + | − | + | + | + |
| − | − | + | − | + | + | − | + | + | + | − |
| − | + | − | + | + | − | + | + | + | − | − |
| + | − | + | + | − | + | + | + | − | − | − |
| − | + | + | − | + | + | + | − | − | − | + |
| − | − | − | − | − | − | − | − | − | − | − |

Table 9 shows the original 12-run Plackett and Burman design. If we take column 11 as the branching column, then the runs (rows) can be split into two groups: group I with the sign of $+1$ in column 11 (rows 2, 3, 5, 6, 7, and 11), and group II with the sign of $-1$ in column 11 (rows 1, 4, 8, 9, 10, and 12). Deleting column 11 from group I causes columns 1–10 to form a supersaturated design to examine $N-2 = 10$ factors in $N/2 = 6$ runs (runs 1–6, as indicated in Table 10). It can be shown that if group II is used, the resulting supersaturated design is an equivalent one. In general, a Plackett and Burman (17) design matrix can be split into two half-fractions according to a specific branching column whose signs equal $+1$ or $-1$. Specifically, take only the rows that have $+1$ in the branching column. Then, the $N-2$ columns other than the branching column will form a supersaturated design for $N-2$ factors in $N/2$ runs. Judged by a criterion proposed by Booth and Cox (27), these designs have been shown to be superior to other existing supersaturated designs. For recent advances in supersaturated design, see Lin (28).

## 4 DESIGNS FOR OPTIMIZATION

### 4.1 Response Surface Designs

We have focused on two-level designs to this point, limiting our model to linear and cross-product (interaction) terms. If we are seeking to optimize a response by

**TABLE 10 The Resulting Supersaturated Design for ($n$, $k$) = (6, 10)**

| No. | $x_1$ | $x_2$ | $x_3$ | $x_4$ | $x_5$ | $x_6$ | $x_7$ | $x_8$ | $x_9$ | $x_{10}$ |
|---|---|---|---|---|---|---|---|---|---|---|
| 1 | + | − | + | + | + | − | − | − | + | − |
| 2 | − | + | + | + | − | − | − | + | − | + |
| 3 | + | + | − | − | − | + | − | + | + | − |
| 4 | + | − | − | − | + | − | + | + | − | + |
| 5 | − | − | − | + | − | + | + | − | + | + |
| 6 | − | + | + | − | + | + | + | − | − | − |

maximizing (or minimizing) it, then we need to fit second-order models with quadratic terms. To do so, we must study at least three levels of a factor. One option is to study each of the $k$ factors at three levels and run all $3^k$ treatments. This experimental design grows in size very rapidly even without replication requiring 27 runs for three factors and 81 for four. Response surface designs generally allow some replication as well as the capability of fitting second-order models while requiring fewer runs than a $3^k$ design. We will discuss central composite designs, although there are other simlar designs such as Box–Behnken (29). These designs are used with quantitative factors.

Recall that we use $-1$ and $+1$ to denote the low and high levels in a two-level design. Then for a quantitative factor, 0 is obviously the level in the middle of this range. A central composite design for $k$ factors consists of a a two-level factorial or fractional factorial ($2^k$ or $2^{k-f}$) design, c centerpoints, and $2k$ axial points. The centerpoints have each factor set to its central value of 0. It is common to use $c > 1$ replications at this location in order to estimate experimental error. There are two axial or star points for each of the $k$ factors in the design. An axial point has one factor set at $\pm\alpha$ and all other factors set at 0. Setting each factor to $-\alpha$ once and $+\alpha$ once leads to the $2k$ axial points. The value of $\alpha$ may be chosen to give the design different properties. If $\alpha = 1$, then we have a face-centered design, as the axial points are located in the middle of each face of the cuboidal design region. Setting $\alpha = \sqrt{k}$ yields a spherical design, as the factorial and axial points lie on a sphere of radius $\sqrt{k}$. Figure 4 is an example of a two-factor central composite design with $\alpha = \sqrt{2}$. If $\alpha = n_f^{1/4}$, where $n_f$ is the number of factorial points, the design is said to be rotatable. In a rotatable design, the variance of the predicted response is the same for all points that are equidistant from the center. See Montgomery (10) for more discussion.

Vega et al. (30) describe a central compostie design used to study the effect of three factors (pH, flurbiprofen concentration, and P188 (a surface coating agent) concentration) on the physicochemical properties of nanoparticles and the drug entrapment efficiency in an ocular delivery system. They used a $2^3$ with $c = 2$ centerpoints, and a rotatable design with $\alpha = 8^{1/4} \approx 1.68$. From Table 11 we see that factor $x_2$ does not appear to affect the mean particle size. Factors $x_1$ and $x_3$ have main effects, but do not appear to interact or have much curvature over the regions studied.

## 4.2 Mixture Designs

In drug development, it is crucial to find the appropriate proportions of active ingredients, buffers, etc. For example, when producing a simple cough syrup, a% of the contents are from component A, b% is from b, and so on. The sum of the components constitutes the whole, so the factor levels cannot be set independently. If there are three factors, $x_1$, $x_2$, and $x_3$ for example, then $x_{i1} + x_{i2} + x_{i3} = 1$ for all $i$. With three factors, the design space is a triangular region. In general, it is known as a simplex. Additional restrictions may occur, such as a requirement of $x_{i1} > 2x_{i2}$, which remove areas from the triangular space.

We discuss an example from Marti-Mestres et al. (31). Three components of a sunscreen were studied, $X_1$ = coconut oil, $X_2$ = Primol, and $X_3$ = isopropyl myristate

***FIGURE 4*** *Central composite design.*

(MIP), and the response was $y =$ oxybenzone solubility. Figure 5 shows the design. Note that each "corner" is included, which is 100% of a single component. The points on the edge represent absence of one component and an equal mixture of the remaining two. The interior points labeled as boxes comprise of two-thirds of one component and one-sixth of the other two. Finally, we have an equal mixture with each

**TABLE 11 Central Composite Design Output**

| | Estimate | Std. Error | *t*-value | Pr($>\|t\|$) |
|---|---|---|---|---|
| (Intercept) | 201.968 | 14.018 | 14.407 | 7e-06 |
| $x_1$ | −21.437 | 5.384 | −3.982 | 0.00727 |
| $x_2$ | 5.432 | 5.384 | 1.009 | 0.35196 |
| $x_3$ | 20.566 | 5.384 | 3.820 | 0.00876 |
| $x_1x_2$ | 13.162 | 7.031 | 1.872 | 0.11037 |
| $x_1x_3$ | 6.013 | 7.031 | 0.855 | 0.42531 |
| $x_2x_3$ | 4.063 | 7.031 | 0.578 | 0.58443 |
| $x_1sq$ | 11.302 | 6.542 | 1.728 | 0.13481 |
| $x_2sq$ | 11.355 | 6.542 | 1.736 | 0.13330 |
| $x_3sq$ | 3.046 | 6.542 | 0.466 | 0.65790 |

***FIGURE 5*** *Simplex design.*

component comprising one-third of the mixture. (For more information on designing and analyzing mixtures, see Cornell (32).)

Due to the constraint that $x_1 + x_2 + x_3 = 1$, the analysis is performed a little bit differently. We generally fit regression models without an intercept term. For this experiment, Marti-Mestres et al. found the following model to fit the data well:

$$y = 11.69x_1 - 0.23x_2 + 13.48x_3 - 7.4x_1x_2 + 4.35x_1x_3 + 7.49x_2x_3 + 54.41x_1x_2x_3$$

Figure 6 shows the response over the mixture region. Using close to 100% Primol ($X_2$) results in $< 0.5\%$ oxybenzone while the percentage of oxybenzone is $> 12.5\%$ for small amounts of Primol. The curvature shown in the plot is indicative of the interactions among the three factors.

## 5 FINAL REMARKS

In this chapter, we have outlined several different DoE techniques that are very useful for achieving quality by design in the pharmaceutical industry. These techniques can be used in conjunction with others such as combinatorial chemistry and high-throughput screening. While high-throughput screening and other methods allow a large quantity of data to be obtained relatively quickly, combining these methods with experimental design techniques allows generation of large volumes of high-quality (easily analyzed) data. Screening designs, including fractional factorials, Plackett–Burman designs, and supersaturated designs, make efficient use of experimental resources to cull a large number of potential factors down to a manageable few. These vital few factors may then be explored in a response surface (e.g., central

***FIGURE 6*** *Contour plot from mixture experiment.*

composite) design or a mixture (simplex) design to find the best combination of factor levels. An example of this sequence is given by Rosso et al. (33). Their studies included a screening DoE to study a broad range of factors and a central composite design to optimize those found to be important. By applying high-throughput methods, they were able to optimize the yield of a reaction by performing a large number of experiments in a short period of time.

There are many other DoE techinques that may be useful in pharmaceuticals that we could not discuss in this brief introduction. For example, the designs (and analyses) discussed in this chapter assume that the treatments were randomly assigned to the experimental units and that the order the experimental units were processed was randomized. This may be difficult or prohibitively expensive in practice. For example, if it is very costly to change reactor temperature, we may set it at one value and vary the other factors. Then we change reactor temperature and vary the other factors in a different random order, repeating for each reactor temperature to be studied. This is an example of a split plot design that requires a different analysis method than described herein.

The experimenter may also be aware that ambient laboratory conditions may vary from day to day. In this case, the results may be more favorable on Tuesday than Monday for reasons unrelated to those of interest in the study. Randomized complete block designs may be used to "block out" the variation due to day-to-day differences, thereby reducing the noise in the experiment.

In addition to finding settings of factors to optimize the mean response, the experimenter may also be interested in finding settings that minimize the variance in the response. Settings that provide desirable mean values of the response with low variation are known as robust settings. Again, different designs and analyses may be used in these robust-design studies.

So while there are many other DoE topics to be explored, we have introduced several designs and analyses that can help the pharmaceutical researcher become a more efficient experimenter. Classical experimental designs, including those popularized in the agricultural sciences, such as factorials and fractional factorials, can play an important role. Others that are more applicable in a laboratory setting, such as mixture designs, have been developed and implemented in food sciences and chemical development. Collectively, these methods can be used to achieve quality by design in the pharmaceutical industry.

*School of Health Sciences, Purdue University, 550 Stadium, Mall Drive, West Lafayette, Indiana*

## 1 INTRODUCTION

Some elements have toxic effects on the human body, and some are essential but have adverse effects at high levels. Monitoring these elements is critical for scientists to assess the association between exposures and health outcomes, and for clinicians to diagnose disease related to exposure (1,2). X-ray fluorescence (XRF) and neutron activation analysis (NAA) are the two main non-invasive methods for *in vivo* and *in vitro* element analysis (3–6). The XRF technology for *in vivo* element measurement will be described in detail in this chapter. In an *in vivo* element measurement, the subject/patient is positioned in front of an XRF device by a trained researcher or technician for a fixed time, and the concentration of the element in a target tissue is determined from an XRF spectrum.

The first *in vivo* XRF measurement was performed in the 1960s to measure iodine in the thyroid (7). Later in the 1980s, a technique to measure iodine in human tissue *in vivo* from X-ray contrast agents was reported (8). Ahlgren et al. (9) made the first bone lead measurement in the 1970s, and since then a number of XRF techniques have been developed, among which XRF bone lead measurement is the most intensively studied and applied. Bone lead has been used to investigate the association between

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing,*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

lead exposure and many health outcomes, such as hypertension, kidney impairment, and cognitive loss (10–15). The *in vivo* XRF technology was also explored to assess occupational or high level environmental exposure to other elements. These elements include but are not limited to Cd, As, Hg, and U.

Another rapidly rising technique, XRF microprobe imaging, will also be briefly described. XRF microprobe imaging maps an element's distribution in human or animal tissue/cells. The imaging process is mostly performed *in vitro* using necropsy or biopsy tissues. Synchrotron radiation XRF (SRXRF) provides excellent trace element sensitivity with its highly intensive beam, and is a valuable microprobe imaging technology (5,16,17). The advanced technologies in synchrotrons and X-ray optics open the door to nano-scale trace element probing, which brings the technology down to the molecular or cellular level (18,19).

Both *in vivo* and synchrotron XRF techniques have made significant contributions to our understanding of the role of trace elements in terms of health effects and biological consequences. There is great potential for both techniques to be improved and broadly applied in the near future.

## 2 DEFINITIONS

### 2.1 X-Ray Fluorescence

XRF is the emission of characteristic "secondary" (or fluorescent) X-rays from a material that has been bombarded with X-rays or $\gamma$-rays. The energies of these fluorescent X-rays are specific to the elements being assessed, and hence the concentration of the element can be calculated from the spectrum collected by a detection system.

### 2.2 Monte Carlo (MC) Simulation

Monte Carlo methods are a class of computational algorithms that rely on repeated random sampling and are widely employed to simulate radiation transportation in materials. For example, to simulate the transportation of photons in a material, the MC program generates random numbers to determine the direction in which the photon travels, the type of interaction between the photons and the material, the energy transition during an interaction, and all the parameters that are required to track the photon. The program tracks the photon until it is absorbed or leaves the relevant area. Normally, millions of photons are tracked to obtain a statistically significant result. The result can be the energy deposited in the material, a signal detected by a detector, or anything else related to the photons that can be theoretically predicted.

### 2.3 Minimum Detection Limit (MDL)

The minimum detection limit is the smallest concentration of an element that can be identified by an XRF system. It is defined as three times the standard deviation of the calculated concentrations for repeat measurements.

## 2.4 Phantom

A phantom is a tissue-equivalent standard doped with a known concentration of the element of interest. Phantoms are manufactured to simulate the *in vivo* measurement or to calibrate the XRF system.

## 2.5 KXRF and LXRF

An orbit electron is knocked out of the shell during the XRF process. If the electron is from the K shell, then the characteristic X-rays produced are called K-X-rays, and the system that detects an element by counting its K-X-ray is called a KXRF system (an LXRF system counts L-X-rays, etc.).

## 2.6 X-Ray Tube

X-ray tubes normally consist of an electron generator, a vacuum tube with a metal target, and a cooling system. The X-rays are produced through the interaction of the electrons with the target, either with the whole atom to produce bremsstrahlung X-rays or with the orbit electron to produce characteristic X-rays.

## 2.7 Polarized X-Ray Beam

Radioisotope- and X-ray tube-induced X-ray sources are isotropic, producing symmetrically distributed polarized X-rays. If a polarizer is placed in front of an X-ray beam, it can select the X-rays polarized on a certain plane and produce a partially or totally polarized X-ray beam. While the X-rays interact with a material, the coherent scattering and incoherent scattering cross-sections are strongly dependent on the angle between the incident beam and the scattered beam. Hence applying a polarized X-ray beam to induce X-ray fluorescence and to detect the characteristic X-rays at the axis of X-ray polarization can significantly reduce the scattered background radiation. One disadvantage of polarized X-ray beam is that the intensity of the beam is greatly reduced after polarization.

## 2.8 Radiation Detector

A radiation detector is used to detect, track, and/or identify radiation particles, such as those produced by nuclear decay, cosmic radiation, or radiation interactions. It works by interacting with the radiation particle and collecting and recording the charges produced. A radiation detector can work as a dosimeter to measure the deposited energy, or as a spectrometer to measure the pulse height distribution of the particles. The detectors described in this chapter are spectrometers that record the signals produced during the interaction of the X-rays and a material or tissue, which include the characteristic X-ray signals.

### 2.9 Radiation Dose

Radiation dose is a measure of the energy deposited in a medium by ionizing radiation. It is expressed as energy deposited per unit mass of medium. Two types of doses are used in this chapter: the organ dose, or the energy deposited in the organ divided by the mass of the irradiated organ, and then multiplied by the weighting factor of the radiation; and the whole body effective dose, which is the organ dose multiplied by the fraction of the organ being irradiated, multiplied by the risk factor of the organ, which is defined by the ICRP (20).

### 2.10 Synchrotron Radiation

Synchrotron radiation is electromagnetic radiation generated by the acceleration of ultrarelativistic (i.e., moving near the speed of light) charged particles through magnetic fields. The synchrotron radiation-induced XRF is called synchrotron XRF and is several orders of magnitude more intense than conventional X-rays as well as being highly focused and polarized.

## 3 THE PRINCIPLE OF XRF

When a beam of X-rays falls onto a given specimen, four basic phenomena result: photoelectric absorption, Compton scattering (also called incoherent scattering), pair production, and Rayleigh scattering (also called coherent scattering) (21). Photoelectric absorption by the elements in the specimen results in the emission of monochromatic X-rays that are uniquely characteristic of the elements.

In the photoelectric absorption process, an incident X-ray undergoes an interaction with an absorber atom in which the X-ray completely disappears and an orbital electron is ejected by the atom from one of its bound shells (K, L, M, etc.). The whole process is subject to the laws of energy conservation as well as momentum conservation, so it cannot take place with free electrons. For X-rays of sufficient energy, the most probable origin of the photoelectron is the most tightly bound shell (K) of the atom. Part of the incident X-ray energy is used to overcome the binding energy of the photoelectron, and the rest is converted to the energy of the photoelectron.

In addition to the photoelectron, the interaction also creates an ionized atom with a vacancy in one of its bound shells. This vacancy is filled through rearrangement of electrons from other shells of the atom, and eventually a free electron is captured from the medium. As a consequence, one or more characteristic X-rays are generated. In some instances, the emission of an electron (called an Auger electron) from another shell may substitute for the characteristic X-ray in carrying away the atomic excitation energy. The incident X-ray could knock out an electron from the K, L, or M shells, and so on, and the vacancy presents in these shells with certain proportions. If the vacancy is in the K shell, then the characteristic X-ray ejected while the electron jumps from other shells to the vacancy is called a K-series X-ray; a vacancy in the L shell produces an L-series X-ray, and so on. Subscript Greek letters (e.g., $K_\alpha$s and $K_\beta$s) indicate the

***FIGURE 1*** *Process of X-ray fluorescence.*

shell and layer from which the electron originates. The energy of the X-ray is determined by the charge, or atomic number, of the nucleus. By measuring the energy and intensity of the characteristic X-rays, we can determine the type and concentration of the element. This is the basic principle underlying XRF measurement of a sample. Figure 1 illustrates the process of X-ray fluorescence.

The other three interactions do not contribute to characteristic X-rays, but Compton scattering and Rayleigh scattering sometimes provide useful information for spectrum and data analysis or produce large background in the energy range of the X-rays. In Compton scattering, an X-ray interacts with an absorber atom and transfers a portion of its energy to an electron. In Rayleigh scattering, the X-ray interacts with all the electrons of an absorber elastically, keeps all its energy, and changes its direction.

## 4 XRF SPECTROMETRY

### 4.1 X-Ray Source, Detection System, and Electronic System

An XRF spectroscopy system consists of three main components: the X-ray source, the detector system, and the electronic system. The X-ray source interacts with the sample and produces characteristic X-rays for target elements; the detector collects the signals; and the electronics process the signals. A spectrum is then displayed on a computer screen and analyzed by a specific software program. The primary goal in developing an *in vivo* system is to achieve the highest sensitivity (lowest detection limit or DL) with an acceptable radiation dose. The selection of radiation source, detection system, and electronics is based on this rule. There are two types of X-ray sources for *in vivo* XRF: radioisotope and X-ray tube. Radioisotope sources have fixed energies and intensities, and X-ray tube sources have flexible energy spectra based on the tube setup and the use of filters. The energy of the source has to be higher than the binding energy of the shell electrons to produce characteristic X-rays for the corresponding shell. The closer the source energy and the binding energy, the greater

the photoelectric cross-section and hence the yield of the characteristic X-rays. While it is important to choose a source with energy close to the binding energy, one needs to be aware that both the X-ray signal count and the background count under the X-ray signal determine the minimal detection limit. Simply put,

$$\mathrm{MDL} \propto \frac{\sqrt{N_{\mathrm{bg}}}}{N_{\mathrm{net}}}$$

where $N_{\mathrm{net}}$ is the net count of X-ray signals, and $N_{\mathrm{bg}}$ is the background count under the X-ray energy range. Improvement of the system means a lower ratio of $\sqrt{N_{\mathrm{bg}}}/N_{\mathrm{net}}$. The ultimate goal of system design is to maximize the signal and to reduce the background.

HPGe detector and Si(Li) detector are two of the most frequently applied detectors for XRF spectroscopy; both have excellent energy resolution (21). The relevant energy range for XRF spectroscopy is 10–100 keV. Most HPGe detectors have high efficiency at energy above 30 keV. Si(Li) detectors are better for energies between 10 and 30 keV. HPGe detectors can be designed for high efficiency in an extra-low-energy range; however, it is difficult to design a Si detector with high efficiency at energy above 80 keV. One disadvantage of these two types of detectors is that they must be cooled by liquid nitrogen to reduce noise. Currently, scientists are working on other types of detectors that can be operated at room temperature or can be cooled by thermoelectronics (22–24). Selection of the detectors is primarily determined by the relevant energy range, resolution of the detector, and price.

There are two types of electronics for XRF spectroscopy (25,26): the conventional analog system and the modern digital system. The analog system digitizes the signals at the end of the signal processing chain, and modern digital signal processing (DSP) digitizes the signals at the beginning of the signal processing chain (after the preamplifier). The DSP approach minimizes the amount of analog circuitry necessary, resulting in increased stability and reproducibility, enhancing energy resolution and increasing signal throughput. The compact digital systems are gradually replacing conventional analog systems. Selection of the electronics is largely based on the energy resolution, signal throughput, and price.

## 4.2 Spectrum Analysis

Once a spectrum is collected, the next step is to analyze and acquire useful information from it. The net count of characteristic X-ray signals is the usual information we need, and there are commercial programs to extract this information. *In vivo* XRF element measurement is a specialized field within X-ray spectrometry, and spectrum analysis programs are generally developed by the investigators in this field. There are many ways to fit a spectrum. The easiest way is to define a function and fit the spectrum with an available algorithm in commercial software. One can also write a program with a theoretically proven algorithm, for example, least square or maximum likelihood, to fit any arbitrary functions (27). Genetic algorithms are also applied to fit the spectrum (28).

### 4.3 System Calibration and Validation

A set of phantoms is manufactured for system calibration. The phantoms are made of material equivalent to the target organ and doped with a known amount of the element of interest. By comparing the net counts of characteristic X-rays of the interested element for the phantom and the unknown samples (human organ/tissue), one can calculate the element concentration in the unknown. If the organ/tissue is buried under another organ/tissue, the radiation attenuation of the overlaying organ/tissue needs to be corrected for. At least one phantom is required to calibrate the system; generally a set of phantoms is measured to construct a calibration line.

Before doing any measurement with a live human being, a system needs to be validated. Other standardized analytical procedures, for example, NAA and inductively coupled plasma-mass spectroscopy (ICP-MS), are used to validate the system (29,30). Normally postmortem organ/tissue samples are used for system validation.

## 5 *IN VIVO* XRF MEASUREMENT OF LEAD IN BONE—INTRODUCTION AND SYSTEM DEVELOPMENT

When an XRF system is designed, two methods can be applied to test its sensitivity and feasibility before a real system is assembled. One can perform a theoretical calculation to obtain the most important values of the system (such as MDL and radiation dose). The calculation of the intensity of characteristic X-rays is illustrated in Appendix A. The calculation of background (coherent and incoherent scattering) follows similar procedure. The second method is to run some Monte Carlo simulations to test and optimize the system. The optimized system is then examined with experiments. In the following sections, different XRF bone lead measurement systems are described, and the development of a KXRF bone lead measurement system is illustrated.

### 5.1 Introduction

Both K- and L-X-rays are suitable for the analysis of lead in bone. To induce K-X-ray fluorescence, the incident radiation has to be above the 88.001 keV K-absorption edge (31). The sources used in K-XRF bone lead measurement system include $^{57}$Co and $^{109}$Cd. The maximum binding energy of the L electrons of lead is 15.870 keV, and the sources used in L-XRF bone lead measurement system include $^{109}$Cd and $^{125}$I, as well as X-ray tube sources.

***5.1.1 In vivo LXRF Bone Lead Measurement Systems*** Feasibility study of the *in vivo* measurement of lead in bone using L-X-ray fluorescence was first investigated by Wielopolski et al. (32). The researchers concluded that $^{109}$Cd and $^{125}$I could be used to detect bone lead by inducing lead L X-rays. Later, Wielopolski (33) conducted a postmortem study to measure bone lead with a $^{125}$I source. The first *in vivo* LXRF study estimated bone Pb values in 45 workers (34).

Later, an X-ray tube source based LXRF system was designed for potential use in children (35,36). This system utilizes polarized X-rays and hence greatly reduced the intensity of the scattering background. Another LXRF system with a secondary target was investigated by Todd (37–39). The polarization of a $^{109}$Cd source to induce lead L X-rays was discussed by Ao et al. (40). Recent research related to LXRF *in vivo* bone lead measurement includes a study to combine K and LXRF methods for the tibia lead concentration (41) and a preliminary study on K and L coincidence spectroscopy (42). The development of a portable LXRF bone lead measurement system is under way (43).

The LXRF method, which is limited to the measurement of lead in the near surface of the bone, has potential for making measurements of short duration with portable equipment. However, the LXRF method has major disadvantages in that its detection limit depends strongly on the thickness of the overlying tissue, and the technique is unlikely to be practical for overlying tissue thicknesses much greater than 5 mm.

***5.1.2 In vivo KXRF Bone Lead Measurement Systems*** The first *in vivo* measurement of bone lead was reported by Ahlgren et al. (9). In this study, researchers utilized γ-rays from $^{57}$Co to excite the K series X-rays of lead in finger bone with a 90° geometry. Later, $^{109}$Cd was found to have significant advantages (44,45). The initial $^{109}$Cd XRF bone lead measurement system consists of a 16 mm diameter HPGe detector with an annular $^{109}$Cd source mounted in front of the detector. An improved system developed by Gordon et al. (46) is based on a larger-area HPGe detector with a diameter of 51 mm and a point $^{109}$Cd source and is the system installed in most of KXRF labs worldwide. Recently a new KXRF bone lead measurement system was developed that consists of a clover-leaf-shaped four-detector array, four digital signal processing units, and a point $^{109}$Cd source (47,48). The high sensitivity of the new system opens the door to the investigation of low-level lead toxicity in children. The development of this new system is summarized in section 411.5.2.

***5.1.3 $^{109}$Cd γ-Ray Induced KXRF Bone Lead Measurement*** In $^{109}$Cd γ-ray induced KXRF bone lead measurement, human tibia, calcaneus, or other bone sites are irradiated to obtain lead K X-rays and then to calculate bone lead concentration. The lead K edge is 88.001 keV. The $^{109}$Cd source emits γ-rays of 88.035 keV with 3.6% intensity (31), just above the energy threshold for the K shell absorption edge in lead, thus maximizing the photoelectric cross-section and hence the X-ray fluorescence yield. The γ-rays interact with a K shell electron in lead, and the electron is ejected. This produces a vacancy in the K shell, which an electron from an outer shell will fill. The energy is released as $K_\alpha$ or $K_\beta$ X-rays with 96% intensity or Auger electrons with around 4% intensity (31). There are also coherent (Rayleigh) scattered γ-rays with energy 88.035 keV and Compton scattered γ-rays with energy range 65.47 keV (180° scattering) to 88 keV for X-rays scattered through very small angles in the forward direction. Figure 2 plots the fluoresced spectrum using a $^{109}$Cd source for K XRF lead measurement of a lead-doped phantom with a concentration of 200 μg/g. The Compton-scattered photons have peak energy of 66 keV, as expected for the 180° back-scattered geometry used. The individual characteristic K X-rays of

***FIGURE 2*** *Spectrum for $^{109}$Cd KXRF lead measurement.*

lead and the coherent peak at 88 keV, coming primarily from scattering from the calcium in the bone, are identified in the spectrum.

A unique feature of using a $^{109}$Cd source and backscattering geometry is that both α peaks and β peaks can be normalized to the coherent peak, making it unnecessary to correct for tissue attenuation and geometry (45) to obtain the lead concentration as a fraction of the calcium concentration.

The system is calibrated by 10 phantoms made of plaster of Paris (a bone equivalent material) with known lead concentrations (μg Pb/g plaster of Paris). The ratios of both ($K_{\alpha 1}$ peak)/(coherent peak) and ($K_{\beta 1}$ peak)/(coherent peak) are calculated from the spectra by a peak-fitting program. The two calibration lines (α calibration line and β calibration line) are the lines of the ratios versus the Pb concentrations. The concentration of Pb in bone for *in vivo* measurement is calculated from these two calibration lines. The final bone lead concentration is an inverse-variance-weighted value from α calibration and β calibration (49,50).

## 5.2 Development of a New KXRF Bone Lead Measurement System

As mentioned above, the ultimate goal in developing an *in vivo* XRF element measurement system is to decrease the MDL while minimizing the radiation dose. In the following section, the development of a new $^{109}$Cd induced KXRF bone lead measurement system is summarized (48). The development of other systems follows a similar procedure.

***5.2.1 Theoretical Calculations*** It is possible to estimate the MDL by manual calculation before a system is assembled. The count of characteristic X-ray signals and the background signals that will be detected by a specific detector are calculated by theoretical formula using interaction cross-sections, detector efficiency, and geometry factors at a fixed geometry, and the MDL is calculated as three times the uncertainty derived from the signal and the background. Manual calculation is difficult for the $^{109}$Cd-induced bone lead measurement system, because there is a large Compton background under the lead K-X-ray peaks, and the counts of the background depend heavily on the Compton broadening effect and the detector reaction function. Because this new system is an improvement of the previous systems, relative MDL (or MDL ratio between the new system and the conventional system) is calculated instead. The new system design is based on an array HPGe detector, with four 16 mm diameter detectors, compared to one 51 mm diameter large detector for the conventional system. We know that $\mathrm{MDL} \propto \sqrt{N_{\mathrm{bg}}}/N_{\mathrm{net}}$. Four detectors produce four times the net signal and four times the background (given a more active $^{109}$Cd source), which gives rise to an MDL ratio of 0.5. The smaller detectors have a better resolution (about 550 ev at the 88.035 keV coherent peak), compared to a resolution of about 750 ev for the conventional large detector. The better resolution accounts for an MDL improvement factor of $\sqrt{550}/\sqrt{750} = 0.86$ resulting from the reduced background. The predicted MDL improvement factor is $0.5 \times 0.86 = 0.43$.

***5.2.2 Monte Carlo Simulations*** MC programs are powerful tools to simulate radiation transportation. They have long been applied to simulate the transportation of neutrons and relatively high energy photons (51–53). In recent years, MC simulation has been successfully applied to the transportation of low energy X-rays. Two of the most frequently utilized MC programs are MCNP and EGS. The old versions of MCNP (MCNP4 and previous versions) and EGS (EGS4 and previous versions) have some apparent defects for the simulation of low-energy X-ray transportation, particularly in the application of XRF system development. For example, the characteristic X-rays are not very well simulated in the programs, and the Doppler broadening of Compton scattering is not simulated at all. The physics of the low-energy X-rays are greatly improved in the latest version of these two programs. To obtain a program that is tailored for one's specific application, the best way is to write one's own program if time and budget permit. The program used to explore the MDL of the new $^{109}$Cd KXRF bone lead measurement system is an in-house program written for radioisotope-induced *in vivo* XRF element measurement, modified to incorporate bone lead measurement (54). MC simulations were performed for both the conventional system and the new array system. Different array designs were simulated, as well as four geometries with different detector sample distance (DSD) and source sample distance (SSD). The simulations test two types of phantoms: the bare phantom made of plaster of Paris to simulate bare bone measurement; and the bare phantom in a soft tissue equivalent plastic phantom to simulate the *in vivo* leg measurement. The absolute MDLs are lower than expected when compared to the MDLs calculated from experiments with conventional systems, possibly because the Compton scattering was not very well simulated. However, the

***FIGURE 3*** *The advanced* $^{109}$Cd *bone lead measurement system.*

MDL ratios provide valuable information on which design and geometry are the best choices.

***5.2.3 Experiments and System Calibration*** The optimized design and setting of the system was chosen through the MC simulations and manufactured by a company producing radiation detectors. The performance of three types of electronic systems was also compared to choose the best one to process the signals from the detectors. The affiliated devices, such as the device to position a patient and the device to hold the $^{109}$Cd source, were manufactured. Figure 3 is a picture of the detection system, which includes an array detector covered under the iron sleeve, a liquid nitrogen Dewar, four preamplifiers, four digital signal processing devices, and a computer. The $^{109}$Cd source is mounted in front of the detector. Experiments were performed on this system to verify the MDL improvement. The average MDLs calculated from the experiments were 6 μg/g for the conventional system and 2 μg/g for the new system. Two calibration lines, one for $K_{\alpha 1}$ peak and one for $K_{\beta 1}$ peak, were produced with the lead-doped phantoms.

***5.2.4 Dosimetry Study*** A small amount of radiation is involved in the *in vivo* XRF element measurement. The researchers or the hospitals containing this type of facility are required to understand the minimal radiation risk to the patient and apply for permission from the human subject committee before using this system. The dose can be estimated from the dose calculated for the conventional system (55), which is equivalent to 5 min of natural background radiation. The new system requires a more active $^{109}$Cd source, about 10 times that of the old source, hence the dose delivered by

the new system is about 50 min of the natural background radiation. Because the geometry of the new system is different from that of the conventional system, and the new system is intended for bone lead measurement in children, a dosimetry study was conducted to accurately estimate the dose to children (56). The result shows that the doses delivered to adults and children are negligible. After the dosimetry study, the researchers applied for and were granted a license to use this system for *in vivo* bone lead measurement.

***5.2.5 In vivo Investigation*** An *in vivo* investigation was conducted with the new system to verify the experimental result. Twenty volunteers were recruited, and bone lead was measured at the tibia site by both the new system and the conventional system. The study confirmed the improvement of the new system over the conventional system, that is, the average MDL of the new system is about 2 μg/g, compared with about 6 μg/g for the conventional system (48).

***5.2.6 Epidemiological and Clinical Significance of the Bone Lead Measurement System, and the Implication of the New System*** There are about 20 KXRF bone lead measurement laboratories around the world, three of which installed the newly developed KXRF system. The KXRF systems in these laboratories made significant contributions to our understanding of the impact of cumulative lead exposure in adult toxicity. The significance of bone lead as a biological marker of lead dose for adults has been reviewed in some previous articles (57–59). Lead exposure has largely declined over the last two decades; nevertheless, lead remains a highly significant environmental toxicant with regard to exposure to children as well as a persistent occupational health problem for hundreds of thousands of workers. It continues to be the focus of intensive screening in pediatric and occupational medicine clinics. In the past, the relatively high MDL of the system and the low overall bone density of children prevented the measurement of bone lead in patients younger than 12–14 years. The new system has a MDL of 2 μg/g and is sufficiently sensitive to measure bone lead levels in children. Using the new system, at least two studies are under way to investigate the association of lead exposure and health effects (particularly neurological effects) among children with bone lead as a biomarker. Historically, clinical research on lead poisoning has focused on prevention of exposure. While such work is important, efforts to mitigate lead's toxicity among children already exposed has received scant attention. By better quantifying the cumulative dose of lead with this new system, we will be able to better identify those children who (i) have the highest exposure; (ii) are most likely to suffer the adverse health effects of lead toxicity; and (iii) are most likely to benefit from medical and social interventions to reduce lead exposure and toxicity. The improved sensitivity of the new system has significance in epidemiological studies, in that it will greatly enhance the significance of the results of analysis with the same population or greatly reduce the size of the required survey population without reducing the statistical significance.

## 6 *IN VIVO* XRF MEASUREMENT SYSTEMS FOR OTHER ELEMENTS

Most of the elements with atomic number $Z$ greater than 15 in the periodic table can be detected at very low levels *in vitro* by XRF. Several factors restrict the *in vivo* measurement of elements. Firstly, the energies of the characteristic X-rays for moderately high $Z$ elements are low, and hence limit detection of these elements to superficial organs such as skin. Secondly, the human body consists mainly of low-$Z$ elements; the relatively high incoherent scattering cross-section in low-$Z$ matrices leads to a large background in measured spectrum and eventually an increased MDL. Thirdly, correction of the geometry and attenuation is difficult. Fourthly, the X-ray source intensity is limited by radiation dose. Despite these limitations, *in vivo* measurements of many elements have been investigated, and such studies are expected to accelerate with each improvement in *in vivo* techniques. In the following section, applications of *in vivo* measurement of elements other than lead are summarized, in the order of their atomic number.

### 6.1 Iron, Copper, Zinc, and Arsenic in Skin

Iron and zinc are essential elements in the human body; copper is neutral; arsenic is toxic. These are moderately high $Z$ elements, with energies of characteristic X-rays ranging from 6 to 12 keV. The intensive attenuation of these low energies in soft tissue limits the *in vivo* measurement of these elements to skin. One application of measuring iron, copper, and zinc in skin *in vivo* is to investigate the association of the concentration of these elements with skin lesions and disorders (60). *In vivo* measurement of iron can also be applied to monitor the efficacy of chelation of Fe, a therapy used to alleviate the tendency of Fe to build up as a result of treatment of the hereditary blood disorder β-thalassemia (61).

The first *in vivo* XRF system to measure iron, copper, and zinc in skin was developed by an Israeli research group (62,63), who used it in normal skin and in various non-malignant and malignant lesions (60). The system is based on a fine-focused X-ray tube with a gold target, and produces 11.4 keV X-rays emanated from a bent crystal monochromator (64). The spectrum is collected by a Si(Li) detector and analyzed by a conventional multichannel system. This technique was improved recently by Farquharson et al. (65–67), who placed different filters in front of an X-ray tube operating at 15 kVp and 23 mA, and optimized the X-ray tube output. The estimated MDLs for iron, zinc, and copper are 20, 10, and 5 μg/g skin tissue, respectively. The reported skin iron and zinc levels among the general population are comparable to MDLs, while the MDL for copper is much higher than the normal physiological skin level (67).

There are concerns about arsenic for both occupational and environmental exposures. In Bangladesh and West Bengal, thousands of people were exposed to water contaminated with high levels of arsenic and developed many types of skin diseases, including cancers. The biomarkers used for arsenic exposure assessment for epidemiology studies include hair and toenails, which are flawed with contamination. In addition, these are not target tissues for arsenic exposure. *In vivo* XRF measurement

of arsenic in skin is a promising method in that skin is a target organ for arsenic. Arsenic binds to the sulfhydryl groups through keratin in skin, and accumulates in the skin. Only one group of researchers studied the feasibility of measuring arsenic in skin *in vivo* by XRF (68–70). Different radioisotope sources and X-ray tube sources were explored with measurement of arsenic-doped skin-equivalent phantoms. MDL of 3.5 and 2.6 μg/g were obtained for $^{109}$Cd source-based and $^{125}$I source-based systems, respectively. The MDL was decreased to 0.7–5 μg/g (based on different skin arsenic distribution models) with an X-ray tube, which is sufficiently sensitive for *in vivo* measurement of arsenic in skin for a moderately or heavily exposed population, with a reported concentration of 0.3–24 μg/g in Bangladesh (71). The i*n vivo*$^{125}$I source-based system was used to measure arsenic in skin in a population with no known arsenic exposure (69). Other studies have used arsenic-doped phantoms. The estimated radiation doses delivered to the subjects are minimal for all these systems. Current studies indicate that XRF could be a valuable tool to assess arsenic in skin among exposed populations.

Currently, our group is in the process of developing a portable XRF device for skin and bone measurement of several elements (43). By combining the proper X-ray tube setting, filter selection and arrangement, and appropriate measurement geometry, this device could be adapted to the measurement of all these elements.

## 6.2 Strontium in Bone

Strontium is a bone-seeking element; over 99% of the body strontium burden is in bone (72). Administration of a small amount of strontium has been reported to have beneficial effects on bone (73,74). However, large amounts of strontium have been found to be detrimental to human health (75,76). The health effects of strontium are still controversial. Strontium has a relatively high concentration in bone, with an estimated level of 32 μg/g bone in Reference Man (77), and hence it is relatively easy to detect by XRF. Three studies have been performed on *in vivo* bone strontium measurement, the first by Wielopolski et al. (78). The XRF system involved was a $^{109}$Cd/$^{125}$I source-based system in a 90° geometry, and the strontium was measured in the tibia. The MDL achieved in this study was about 15 μg strontium/g bone. Later, Pejovic-Milic et al. reported an *in vivo* study on 10 environmentally exposed subjects with a similar system (79). The average MDL for this $^{109}$Cd-induced measurement system was 52 μg strontium/g bone. Five of the ten subjects had strontium concentrations lower than the MDL. Zamburlini et al. (80,81) improved the system with a $^{125}$I source and an optimized geometry, and obtained a detection limit of 5 μg strontium/g bone. The Zamburlini system was sensitive enough to detect the individual bone strontium in all 22 environmentally exposed subjects. The portable XRF system mentioned above is sensitive enough to obtain the strontium peak within 30 s (as opposed to 30 min for most of the *in vivo* measurement systems) with an acceptable radiation dose (43). The MDL of this portable system is still under investigation. The available data indicate that *in vivo* XRF bone strontium measurement is sufficiently sensitive for exposure assessment among the general population.

## 6.3 Silver in Skin

Health effects of occupational silver exposure include gastrointestinal irritation, renal and pulmonary lesions, and argyria and argyrosis, in which discoloration occurs in skin and in the eye (82). Argyria and argyrosis are of greatest concern. *In vivo* measurement of silver in skin, if proven feasible, will provide valuable information on the association between silver exposure and argyria, and possibly identify individuals at risk of the disease. There is only one study of *in vivo* measurement of silver in skin (83). This system is based on a $^{125}$I radioisotope source, and the measurements were taken on skin-mimic phantoms. The estimated MDL is 3–4 μg/g with 10–20 min measurement. There are little data to date regarding typical concentrations of silver in skin among exposed or non-exposed populations. Based on the available data, which report skin silver concentrations of 72 μg/g for an argyria patient (84) and a derived skin concentration of 1.4–43 μg/g after an acute inhalation of silver to induce argyria (83,85), the MDL with the current XRF system is encouraging for use among an exposed population.

## 6.4 Cd in Kidney and Bone

Kidney and liver are target organs with relatively high concentrations of cadmium, and contain over 50% of the body burden (86). Cadmium exposure is related to renal disease, bone disease, and can affect pulmonary function and neurological function (87). Over the past 30 years, both *in vivo* NAA and *in vivo* XRF techniques have been developed to non-invasively measure cadmium levels in the liver and kidney (88,89). Two systems were developed by the same group of scientists to measure cadmium in kidney with XRF. The first system generates Cd characteristic X-rays ($K_{\alpha 1,2} = 23.1$ keV) with an $^{241}$Am radioisotope source (90). The source is set up at the side of the person measured, and a Ge(Li) detector is located at the back of the subject. The MDL for the system is strongly influenced by the dorsal depth from the subject's back to the kidney surface and ranges from 20 to 40 μg/g for depths between 30 and 40 mm. A more sensitive system was developed a couple of years later (91) based on excitation of Cd by partially polarized X-ray beams from an X-ray therapy unit. The MDL varies between 3 and 20 μg/g for distances between the skin and the kidney surface of 30 to 70 mm. Borjesson et al. (92) proposed a system with an expected detection limit of 1 μg/g by optimizing the X-ray spectrum from a novel X-ray tube. A few studies have used XRF to examine the health effects of cadmium exposure (93). All studies focused on occupationally exposed workers except one (94), in which significant differences in cadmium concentrations in the kidneys were detected between non-occupationally exposed smokers and non-smokers. These results suggest that *in vivo* XRF measurement of cadmium in kidney is useful tool for cumulative dose assessment in occupationally exposed workers, but the technique still requires substantial improvement and validation for cumulative exposure assessment in the general population.

Bone is another target organ for Cd. Skeletal damage caused by chronic Cd exposure has been noted in humans (95) and in experimental animals (96), the

mechanism for which has been reviewed in several papers (97–99). The concentration of Cd in bone is relatively low even among exposed populations, with reported values of 0–1.5 μg/g (100,101). Two studies have been conducted to investigate the feasibility of measuring Cd in bone *in vivo* with XRF. Carew et al. (102) conducted a pilot study on the radioisotope source-based system and concluded that MDL with a $^{109}$Cd source in backscatter geometry was superior to several other possible geometries and excitation sources. Chettle (103) analyzed the capabilities of two HPGe detection systems and a lithium-drifted silicon (Si(Li)) system to detect bone Cd X-rays emitted through $^{109}$Cd sources and obtained an optimized MDL of 2.1 μg/g for 3 mm of overlaying soft tissue. Cadmium-doped standards were used in both studies, and no *in vivo* measurements were made. Current XRF techniques require improvement to assess bone cadmium in occupationally exposed populations.

## 6.5 Iodine in Thyroid

Iodine is as easy to detect as strontium due to its high concentration in thyroid. Knowing the amount of iodine stored in the thyroid may contribute to our understanding of thyroid diseases, the uptake and release of iodine from the thyroid, and possibly to the prediction of treatment outcome. The first *in vivo* iodine measurement in thyroid was reported in the 1960s (7). Several studies performed later used similar X-ray tube-based systems (104–106). One recent study reinforced the contention that XRF is a valuable method to determine the iodine content in thyroid (107). However, to improve accuracy, care must be taken to obtain precise knowledge of the measurement geometry, that is, the exact location of the thyroid and the measurement (108,109). All the described systems are sensitive enough to detect iodine in thyroid in the general population, though correction for geometry and attenuation still requires further investigation.

## 6.6 Platinum and Mercury in Kidney

People are exposed to platinum through mining and cytotoxic drugs (cisplatin and its transplatin analogues). Mercury exposure occurs in the general population from diet and dental amalgams. Occupational exposure is generally much higher, from sources such as mercury and gold mining, chloralkali and thermometer factories, and dental amalgam handling. Both platinum and mercury are toxic. Even low-level exposure can cause kidney disease and malfunction of other organs (110,111). The XRF measurement system for *in vivo* studies of platinum and mercury in the kidney is essentially that used for the measurement of cadmium in kidney (112). The average MDL of this system is 8 μg/g for platinum (113) and 26 μg/g for mercury (114,115). In Börjesson's study, half of the exposed workers had kidney mercury higher than the MDL, and none of the referents' values exceeded the individual MDL (114). The current technique for mercury is restricted to moderately and heavily exposed populations. It is a potentially valuable tool to assess platinum in tumors of patients treated with platinum-related cytotoxic drugs.

### 6.7 Uranium in Bone

Uranium, which accumulates in bone and kidneys, is a potential health hazard. Occupational exposure is the primary concern. The rise of the nuclear industry, which is increasing the demand for uranium mining, is expected to make the health effects of uranium a more significant issue. A $^{57}$Co-source-based XRF bone uranium measurement system was proposed by O'Meara et al. (116,117), whose system has an MDL of 20 μg uranium/g bone mineral. That MDL is more than three orders of magnitude greater that the 0.01 μg/g bone uranium level reported for the general population and more than one order of magnitude greater than the maximum of 2 μg/g for occupationally exposed populations (116). Current XRF techniques are not sensitive enough for measurements of even highly exposed subjects.

## 7 SUMMARY AND FUTURE DEVELOPMENT OF *IN VIVO* XRF ELEMENT EXPOSURE ASSESSMENT

Table 1 presents the characteristics of most XRF systems for *in vivo* element measurement. Among these techniques, measurements of iron and zinc in skin, strontium and lead in bone, and iodine in thyroid are applicable to general population; measurements of arsenic and silver in skin and cadmium, platinum, and mercury in kidney are applicable to moderately and highly exposed population; measurements of copper in skin and cadmium and uranium in bone demand further improvement.

Many techniques and methods can be applied to improve the *in vivo* XRF element measurement system. Advanced detectors and electronics can be adopted from other applications. Capillary optics can be used to focus the X-rays to a small beam with

**TABLE 1 Applications of *In vivo* Element Measurement**

| Element | Site | MDL (μg/g)* | Current Status |
|---|---|---|---|
| Iron | Skin | 20 | Applicable to general population |
| Copper | Skin | 5 | Demands further improvement |
| Zinc | Skin | 10 | Applicable to general population |
| Arsenic | Skin | 0.7–5 | Applicable to highly exposed population |
| Strontium | Bone | 5 | Applicable to general population |
| Silver | Skin | 3–4 | Applicable to highly exposed argyria patients |
| Cadmium | Kidney | 3–20 | Applicable to occupationally exposed population |
| | Bone | 2.1 | Demands further improvement |
| Iodine | Thyroid | 50 μg/mL | Applicable to general population |
| Platinum | Kidney | 8 | Applicable to patients treated with platinum related drugs |
| | Tumor | | |
| Mercury | Kidney | 26 | Applicable to moderately and heavily exposed population |
| Lead | Bone | 2 | Applicable to general population |
| Uranium | Bone | 20 | Demands further improvement |

*Latest MDL.

a relatively high intensity. For the X-ray tube source, the use of a different target or a secondary target can be explored, and different filters can be applied to optimize the X-ray source. Polarized X-rays can also be considered to reduce the background. Monte Carlo simulation can always be employed to determine the best set-up.

While technical improvement is an important issue, it is also critical to establish an effective connection between the technique developed and the end user. The advance of the technique and the direction of the improvement will be largely driven by the demand of the technique.

## 8 SYNCHROTRON RADIATION-INDUCED X-RAY FLUORESCENCE IN MEDICINE AND BIOLOGY

Another rapidly growing application of XRF in medicine and biology is microprobe imaging, also referred to as synchrotron microprobe imaging because the fluorescing source is produced by a synchrotron. The use of synchrotron radiation for XRF has several advantages over an X-ray tube or a radioisotope source (118), including: a much higher intensity, a polarized X-ray source, and a sub micro-scale source beam. The disadvantage is that the access to a synchrotron is limited.

### 8.1 Principles of Synchrotron XRF

The principles of synchrotron XRF are similar to those of XRF induced by conventional radioisotopes or X-ray tube sources. The main difference is that the X-ray source is generated by the acceleration of charged particles. Conventional synchrotron uses a ring magnet to guide the particles in an orbit, with a radio-frequency cavity to accelerate the beam in a periodic manner. Modern synchrotron utilizes a storage ring to accelerate the particles. The straight sections in the storage ring are used for inserting periodic magnetic devices (wigglers) that force the particles into a sinusoidal path. The particles are then further accelerated in a coherent fashion to produce high energy, high intensity X-rays. The size of the X-ray source is determined by the size of the particle bunch that is in orbit around the ring, and it can be minimized to a sub-micro-scale size using X-ray optics. The synchrotron is described in detail elsewhere (119). The synchrotron X-ray beam can be tailored to an intensive monoenergy bean by placing a monochromator in front of the source. The intensity of the X-ray source produced by the synchrotron is several orders higher than that of the highest-powered X-ray tubes, and hence synchrotron XRF is several orders more sensitive than conventional XRF. The X-ray is concentrated in the plane of the electron orbit and hence it is highly polarized in the same plane. The polarization of the X-ray beam further increases the sensitivity of the synchrotron XRF because of the reduced background from scattered coherent and incoherent radiation.

### 8.2 Element Mapping with Synchrotron XRF

The characteristics of the synchrotron beam make it a perfect choice to explore metal or trace element distributions. Its small beam size allows elements to be scanned at

a superior spatial resolution; its high intensity enable the mapping of some thousand points, collected within a reasonable time period. Two samples with synchrotron XRF are discussed below, representing application at micro- and cellular scales.

#### *8.2.1 Distribution of Metals and Trace Elements in Tissues*

Distribution of metals and trace elements in tissues can be explored with synchrotron XRF (120–123). In *in vivo* XRF measurement, the concentration of the element is calculated in a relatively large volume of tissue; synchrotron XRF tells you how the element is distributed. During the scanning process, an extra-thin slice of tissue sample (on the order of μm) is positioned in front of the source, and the source scans the slice in a 2D manner. The 2D composition of the elemental distribution is reconstructed with a specific software package. Depending on the source size and the demands of the application, the spatial resolution ranges from tens of μm to 1 mm. The tissues of interest include breast, bone, heart, brain, and other sites. With this technique, researchers have found elevated metal levels in breast cancer cells (124). Zoeger et al. (125) reported elevated lead and zinc concentrations at the tidemark of bone, where bone remodeling takes place. Szczerbowska (126) discovered differences in elemental composition of brain tissues between Parkinson's disease cases and a control group. The information obtained by synchrotron XRF element mapping in these areas provides valuable information in understanding the significant role metals and trace elements play in human health, whether beneficial or detrimental.

#### *8.2.2 Distribution of Metals and Trace Elements in Cells*

Synchrotron XRF microprobe imaging is now able to map the distribution of metals and trace elements in cells (127). Palmer et al. (128) studied zinc and calcium distribution in heart muscle cells. McRae et al. (129) investigated elemental maps for mouse fibroblast cells. Metal concentrations in metal-binding proteins were also explored (130). Though the number of studies in this area is small, this technique has great potential to become a valuable biotechnology tool, as summarized in Paunesku et al.'s (131) comprehensive review.

### 8.3 Future Development

Improvement of synchrotron XRF systems includes enhancement of the source, advancement of detectors and electronics, and extensive application of MC simulations. Establishment of a productive connection between the technique developed and the medical and biological community is also very important.

## ACKNOWLEDGEMENTS

The author is grateful to Dr. Lee Grodzins for correcting some of the physics concepts, providing valuable comments on the content, and contributing in Fig. 4 and formula in Appendix A. The author would also like to thank Paul Guttry for her comprehensive editing.

***FIGURE 4*** *A schematic diagram of an in vivo element measurement setup with X-ray tube.*

## APPENDIX A: CALCULATION OF INTENSITY OF CHARACTERISTIC X-RAYS

Figure 4 illustrates a setup for *in-vivo* element measurement with an X-ray tube. The target organ is B, and there is an overlaying tissue A on top of B. The following equations calculate the intensity of characteristic X-rays of element E from target organ B. A monoenergetic, incident X-ray or γ-ray beam is assumed; the fluorescing and fluoresced radiations enter and exit perpendicular to a uniform overlay tissue surface; geometrical and detection efficiencies are subsumed in the constant K. At thickness t of target organ B, the characteristic X-rays produced over thickness of d$t$ and collected by the detector is given by

$$\begin{aligned} \mathrm{d}(I_{\mathrm{E,X}}) = K \times I_0 \times \mathrm{e}^{-\mu_{\mathrm{in,A}} \times t_{\mathrm{A}}} \times \mathrm{e}^{-\mu_{\mathrm{in,B}} \times t} \times \mu_{\mathrm{PE}} \times Y \times f_{\mathrm{E}} \times b \times \mathrm{d}t \\ \times \rho_{\mathrm{B}} \times \mathrm{e}^{-\mu_{\mathrm{X,B}} \times t} \times \mathrm{e}^{-\mu_{\mathrm{x,A}} \times t_{\mathrm{A}}} \end{aligned} \tag{1}$$

Where $I_{\mathrm{E,X}}$ is the number of characteristic X-rays measured by a detector; $I_0$ is the photon flux ($\mathrm{cm}^{-2}$); $t_{\mathrm{A}}$ is the thickness of overlaying tissue A; $\mu_{\mathrm{in,A}}$ is linear attenuation for incident photons in tissue A; $\mu_{\mathrm{X,A}}$ is linear attenuation for characteristic X-rays in tissue A; $\mu_{\mathrm{in,B}}$ is linear attenuation for incident photons in target organ B; $\mu_{\mathrm{X,B}}$ is linear attenuation for characteristic X-rays in target organ B; $\mu_{\mathrm{PE}}$ is the cross-section for photoelectric interaction ($\mathrm{cm}^2$/g); Y is the yield of characteristic X-ray; $f_{\mathrm{E}}$ is the concentration of element E given in g/(g organ B); b is the irradiated area ($\mathrm{cm}^2$); $\rho_{\mathrm{B}}$ is the density of organ B. Integrate the above equation over the thickness of target organ B, $t_{\mathrm{B}}$

$$\int_0^{t_{\mathrm{B}}} \mathrm{d}(I_{\mathrm{E,X}}) = K \times I_0 \times \mathrm{e}^{-(\mu_{\mathrm{in,A}} + \mu_{\mathrm{X,A}}) \times t_{\mathrm{A}}} \times \mu_{\mathrm{PE}} \times f_{\mathrm{E}} \times b \times \rho_{\mathrm{B}} \times \int_0^{t_{\mathrm{B}}} \mathrm{e}^{-(\mu_{\mathrm{in,B}} + \mu_{\mathrm{X,B}}) \times t} \mathrm{d}t \tag{2}$$

Calculate the integration,

$$I_{E,X} = K \times I_0 \times f_E \times b \times \frac{\mu_{PE} \times \rho_B}{\mu_{in,B} + \mu_{X,B}} \times \left[1 - e^{-(\mu_{in,B} + \mu_{X,B}) \times t_B}\right] \times e^{-(\mu_{in,A} + \mu_{X,A}) \times t_A} \tag{3}$$

When the thickness of target organ B is sufficiently large, that is, the target organ B is "infinitely" thick, the number of the X-rays that can be measured by a detector is then given by

$$I_{E,X} = K \times I_0 \times f_E \times b \times \frac{\mu_{PE} \times \rho_B}{\mu_{in,B} + \mu_{X,B}} \times e^{-(\mu_{in,A} + \mu_{X,A}) \times t_A} \tag{4}$$

## 1 INTRODUCTION

### 1.1 Examples

*Example 1-1:* During a fermentation process, a sensor registers temperature measurements at regular time intervals, resulting in a large dataset for each fermentation batch. A process chemist who is new to the factory is given data from a couple of batches to familiarize himself with the way the process behaves with regard to temperature. Looking down the long list of data is not helpful, he needs some tools.

*Example 1-2:* A pharmaceutical company is considering two types of tanks for their fermentation process. It is believed that the yield from one tank is higher than from the other, but the company would like to investigate this before deciding which tank to use.

*Example 1-3*: Measurements of assay from two stability studies, each consisting of three batches, are analyzed together. The analysis is supposed to show how an assay develops over time, if the development is the same for batches in the same study or, if possible, the same in all batches.

*Example 1-4:* In a production process, one wants to raise the yield. There are a number of factors that may influence the yield, such as holding time, feeding speed, and various conditions of the raw materials. Which of these actually has an influence, and how large the influence is, has not been established. While a lot

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing,*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

of personal opinions exist among the process operators, there are few data outside the current set-point.

*Common background for the examples:* All of these examples call for a tool from the statistical toolbox, be it to summarize and graphically depict data, or be it to test a hypothesis, build a model, or design an experiment.

### 1.2 Introduction of the Tool

To the academic statistician, statistics is a branch of mathematics. To the practitioner, statistics is a tool to better understand the numerical data that are abundant in a modern production environment. This chapter is written for the practitioner. It is an introduction to a useful toolbox, lining up the different tools side by side. If you have an overview of the toolbox, you avoid resembling the man with the hammer to whom everything looks like a nail. Instead, there are a number of different tools for different situations. Sometimes, different tools can be used for the same situation. There is no absolute right and wrong in the choice. In general, statistics is not about absolute rights and wrongs. It is a set of tools to help you distinguish the probable from the improbable and find the most compelling explanation for your observations.

### 1.3 Examples Continued

*Example 1-1:* Descriptive statistics, like mean and standard deviation, and graphs are helpful in this situation. See the paragraphs on these two subjects.

*Example 1-2:* See the paragraph on hypothesis testing.

*Example 1-3:* This example calls for a model of the data. See the paragraph on mixed models.

*Example 1-4:* Statistics does not start with the data. If you plan to collect data systematically through experiments, it makes sense to use a statistical tool to set up your experiments in the way that gives you the most information for the data collection effort. See the paragraph on design of experiments.

## 2 TYPES OF DATA

### 2.1 Examples

*Example 2-1:* Measurements of strength of insulin in insulin vials are made as part of the quality control before release of the batch.

*Example 2-2:* Switches used in the production of a medical device are examined by quality control and sorted into good items and scrap.

*Example 2-3:* Subjects entering a clinical trial have their body mass index (BMI) measured. However, the exact BMI is not registered, only the categories obese ($\text{BMI} > 30$), overweight ($25 < \text{BMI} \leq 30$), normal ($17.5 < \text{BMI} \leq 25$), and underweight ($\text{BMI} \leq 17.5$). In the study the ethnicity of the subject is also registered. It can be "Caucasian," "African," "Asian," or "Other."

## 2.2 Introduction of the Tool

There are three types of data: continuous data, discrete data, and categorical data. Continuous data are data measured on a continuous scale. The strength measurement in Example 2-1 is an example of continuous data. Discrete data can assume all integer values ($\ldots, -1, 0, 1, 2, \ldots$). Both continuous and discrete data can be placed in an infinite number of categories. Categorical data, on the other hand, can only be placed in a finite number of categories. Categorical data can be ordered or unordered. The BMI groups in Example 2-3 are ordered data since a person in the overweight group is known to have a larger BMI than those in the normal group and a smaller BMI than those in the obese group. The grouping of the subjects by their ethnicity is obviously unordered. When there are only two categories, as in Example 2.2, the notion of order is meaningless. Sometimes continuous data are rounded so much that they appear to be categorical. If that is the case one should try and get some more decimals; otherwise, the data have to be analyzed as categorical. It is important do determine which type of data one is working with since the type is key to the distribution that could describe data and which kind of analysis one should make. For instance if one has height measurements for children as the variable of interest and age measurements as the explanatory variable then dependent on the age measurements, one could make different kinds of analyses. If the age measurements were only in two or three categories, a one-sided ANOVA (ANalysis Of VAriance) model could be fitted, and if the age measurements varied more, e.g., if they were continuous, a linear regression could be made.

# 3 GRAPHS

## 3.1 Examples

*Example 3-1:* From a fermentation process, data on oxygen and sugar consumption are recorded at regular time intervals. One wants to detect patterns in the data over time and understand how the consumption data relate to process parameters such as temperature and pH, which can be adjusted.

*Example 3-2:* In a clinical study, a number of data are obtained from patients, including HbA1c, average fasting glucose, and average post-prandial glucose before and after treatment. The patients have received different doses of the medication. For each subject, a number of background variables have been recorded, e.g., gender, age, BMI, and time since diagnosis.

*Example 3-3:* A screening test for cancer is offered countrywide, but the number of people accepting the offer differs widely between different counties. In a survey, the number of tests conducted per year is determined and related to the number of eligible inhabitants for each county. One wants to understand the patterns of the variation and hopes to discover a reason for the different acceptance of the test.

*Common background for the examples:* In all examples, one approaches the data with a desire to explore and understand whatever is in the data. This can be a situation

where one does not have a specific question to the data that warrants a test. But also when one has planned a test, it makes sense to start with a graph to get a feeling for the data. Once knowledge of the structure in the data has been obtained, it needs to be conveyed to other people who have not participated in the analysis and wish to quickly and easily gain an understanding of the results.

## 3.2 Introduction of the Tool

As in other fields of exploration, one of the most important things one can do is to get to the scene and see for oneself. To see your data, you need to arrange them graphically. There are a wide range of graphs that will highlight different aspects of the data. You can use them to scan groups of data, rather than single observations at a time. Graphs are also a strong tool for communicating your findings, as they typically do not require any familiarity with statistical procedures.

## 3.3 Types of Graphs

***3.3.1 Time Plots*** Patterns occur often over time. If your data have an inherent time order, plot them in this order. If the time points of data collection are unequally spaced, reflect this spacing on your time axis. For continuous data, use dots, possibly connected (see Fig. 1). For categorical data, you can use stacks of colored bars that reflect either the number of observations or the percentage of observations in each category (see Fig. 2). You can include several series of data, e.g., the oxygen and sugar consumption from Example 3-1, in the same time plot to see whether the variables' variation over time is related.

***FIGURE 1*** *Time plot for numerical data.*

***FIGURE 2*** *Time plot for percentages.*

***3.3.2 Scatter Plots*** To explore the relationship between pairs of continuous data, plot them as dots in a coordinate system with one variable on the x-axis and the other on the y-axis (see Fig. 3). You can then nicely see correlations. If time may play a role, you can connect the dots in time order to see the process wander through the plane that the variables span. You can also construct scatter plots with three axes for three variables, but these can be difficult to interpret on a two-dimensional computer screen or piece of paper.

***3.3.3 Group Plots*** If your data belong to different categories, e.g., male-female, or fermentor A, B, and C, and are on a continuous scale, draw them side by side (see Fig. 4). You can include lines indicating the averages, ranges, standard deviations, etc. You can then easily see whether, e.g., one category stands out from the others, or the categories fall into groups that are similar.

***FIGURE 3*** *Scatter plot.*

***FIGURE 4*** *Group plot.*

***3.3.4 Bar Charts*** For categorical data belonging to different categories, proceed as for a group plot, but use bars instead of dots (see Fig. 5).

***3.3.5 Pie Charts*** These are useful to show percentages, especially if there are few categories, or few of the categories account for a large part of the data. Wedges of a circle are colored such that the area for each category corresponds to the percentage of that category (see Fig. 6).

***3.3.6 Histograms*** If you want to check the distribution of a single continuous variable, divide the range of data into a suitable number of categories or bins. Then count how many observations there are in each bin. Set off the categories on a horizontal axis and draw columns whose height corresponds to the number of observations (see Fig. 7). Draw the columns without spaces between them. If, e.g.,

***FIGURE 5*** *Bar chart.*

***FIGURE 6*** *Pie chart.*

your data are close to normally distributed, the columns will form a bell shape. A histogram will show you whether, e.g., you have a skewed distribution or heavy tails.

***3.3.7 Other Charts*** While most of the charts mentioned above are widely applicable and easily accessible in statistical software, you need not let yourself be restricted by this list. Special datasets may be best represented in a different way that takes some specific quality of the data into account. For example, if the dataset involves data representing some position in space, you may want to reflect this by arranging representations of the data in space (see Fig. 8).

## 3.4 Traps

***3.4.1 First Glance Conclusions*** Graphs typically highlight one or few specific aspects of the data. This is their strength, as it helps you focus on this aspect. But it is also their weakness, if it removes an important aspect of the data from focus. It is therefore recommended to represent data in various graphs during

***FIGURE 7*** *Histogram.*

***FIGURE 8*** *Graph for spatial data: Filling height in a tank depending on time.*

exploration, just as you would turn an unfamiliar object in your hands to see it from different angles.

***3.4.2 Scaling the y-Axis*** A widespread misuse of graphs consists in constructing bar charts, or time plots for categorical data, where the y-axis does not start at 0, but at a random point below the lowest data point. Small differences can be blown up to look enormous.

***3.4.3 Depicting Only Part of the Data*** You can also create a misleading impression by choosing the data for a graph from a narrow range. For example, if showing a time plot of some continuous data from a short time period, you can create the impression of large fluctuations, while in fact the fluctuations are small as compared to the normal process range.

***3.4.4 Setting Graphs with Corresponding Axes, but Different Scales Side by Side*** If two graphs with similar data are placed close to each other, you can prompt comparisons that do not reflect the actual correspondence between the two if the axes use different scales. People will typically look at the data and not check the surrounding information unless prompted to do so. So you should ensure that they need not check to understand the data.

***3.4.5 Overloading a Graph with Graphical Elements*** Graphs in news media typically contain a large number of graphical elements, part of which convey information and part of which only have decorative purposes. This is fine as long as the view to the data is not obscured by the graphics. In general, the fewer elements a graph contains, the easier it is to grasp. You can therefore make your graph easier accessible as a communication tool if you restrict yourself to elements that

convey information. These considerations start already at the choice between two- and three-dimensional bars for a bar chart: Both contain the same information; the third dimension is a purely decorative element.

### 3.5 Examples Continued

*Example 3-1:* Oxygen and sugar consumption can be shown in time plots, possibly in the same plot with different axis. The relation between the two variables can be shown in a scatter plot. Also, scatter plots can be used to show oxygen consumption vs. temperature, oxygen consumption vs. pH, and so on. The four graphs can be arranged in a matrix, with corresponding axes having the same scales.

*Example 3-2:* A typical graph to consider shows the difference between ending and starting HbA1c plottet against dose. One may want to subdivide each dose group into the two gender groups, or into groups relating to BMI. One can also draw a scatter plot for the difference between ending and starting HbA1c vs. the non-categorized BMI or vs. the starting HbA1c. The same can be done for average fasting glucose and average post-prandial glucose.

*Example 3-3:* One can show the survey results nicely by coloring a map of the country. Each county is shown in a color corresponding to, e.g., the number of yearly tests per 1000 inhabitants. Colors are assigned to ranges of test numbers such that the ordering becomes clear; e.g., one can use different intensities of the same color. One may also be suggestive in coloring: Use red for the category of figures that is least desired by the customer to the analysis, and green for the category that is most desired. One can then add other relevant spatial information, e.g., the location of hospitals that may have an influence.

## 4 DESCRIPTIVE STATISTICS

### 4.1 Examples

*Example 4-1:* A pharmaceutical company is considering two different suppliers of glass vials for their pharmaceutical product. They get a sample of 1000 vials from each of the two vial producers and want to compare the two samples of vials. The vials are described by their length, their diameter, the thickness of the glass, etc.

*Example 4-2:* In a clinical trial, one compares two treatments for obesity. Some of the important characteristics of the subjects participating in the trial are gender, height, weight (before and after treatment), and BMI (before and after treatment).

*Common background for the examples:* In the above examples, one wants to describe a sample or a population by some well-defined characteristics that are of interest; e.g., in the clinical trial, the weights are of interest. However, the description should be in a summarized form, not a list of the weights for all subjects, since it is mostly impossible to get an overview from a raw list of data.

## 4.2 Measures of Location

The level of a specific characteristic in a sample, e.g., vial length in Example 4-1, can be described by different measures.

***4.2.1 Average*** This is the sum of the measurements divided by the number of them:

$$\bar{x} = \frac{1}{n}(x_1 + \cdots + x_n) = \frac{1}{n}\sum_{i=1}^{n} x_i$$

where $n$ is the number of observations and $x_i$ is measurement $i$.

***4.2.2 Median*** This is the value where half of the observations have a value that is smaller than or equal to this value. To determine the median, one should order the observations in ascending order. If the number of observations is equal, the median is the mid-point value between the two middle observations; e.g., if there are 10 observations, the median is midway between the values of observation 5 and observation 6. If the number of observations is unequal, the median is exactly the observation in the middle.

## 4.3 Measures of Variation

When the level/location of a characteristic is known for a sample, it is also desirable to know how much variation there is in the sample. For example, in Example 4-1, the two producers of vials may have the same average vial length, but the variation in the two samples may be quite different and very important to the pharmaceutical company.

***4.3.1 Variance*** The variance is calculated as $\frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2$, where $n$ is the number of observations and $x_i$ is measurement $i$, and $\bar{x}$ is the average of the $n$ observations. The variance is a sort of average of the squared distance between the observations and their average. Using the above definition, the variance is only well defined if there is more than one observation; otherwise, one will divide with zero, which is impossible. However, in some statistical textbooks, the divisor is $n$; in that definition the variance is zero if there is only one observation. Normally, the variance is always larger than zero. The variance is often used in statistical calculations, but as a descriptive measure, it is not that useful since the scale is the squared natural scale; e.g., in Example 4-2, the measurements of weights could be in kilograms (kg) and then the variance would be in kilograms squared ($kg^2$). As a descriptive measure of the variation, the following is used.

***4.3.2 Standard Deviation*** This measure is given as $\sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2}$, which is the square root of the variance. The standard deviation is measured on the same scale as the average – the scale that the observations are made on.

***4.3.3 Range*** The range is calculated as the difference between the highest and the lowest value of the observations. It is a very crude measure of the variation in the sample but very easy to calculate.

There are other measures such as skewness and mode that can be of interest. For a description of these, refer to [1].

## 4.4 Traps

***4.4.1 Outliers*** When one describes the sample of interest, one should be aware of outliers (see 6.4.3) and their influence on the different descriptive statistics. The average is sensitive to outliers. For example, if there is an observation with a very high value, the average will be quite high compared to what it is if the outlier is removed. The median is far more robust since the removal of a single observation (the outlier) will not change the median very much. It can therefore be advisable to state both the median and the average. If they are close, the distribution the observations stem from is symmetric, and there are no outliers. Both measures of variation are sensitive to outliers.

***4.4.2 Small Samples*** If the number of observations in a sample is small, the descriptive statistics may not be representative for the entire population that the sample is drawn from. Also, it will be hard to determine if there are any outliers (see 6.4.3)

## 4.5 Examples Continued

*Example 4-1:* Descriptive statistics should be calculated for each of the measurements (vial length, glass thickness, etc.) for each of the two samples.

*Example 4-2:* For each of the two treatment groups, descriptive statistics should be found for height, weight, etc. The two groups might further be split in groups defined by there sex. It would make sense to investigate that treatment differences are not due to differences in, e.g., height or weight in the two treatment groups.

# 5 DISTRIBUTIONS

## 5.1 Examples

*Example 5-1:* A supplier of components used in a medical device plans to deliver a description of his components. He would like to state an interval within which the length of the components will be with a given certainty.

*Example 5-2:* As a part of a quality control program, a sample is taken from every produced batch of a medical device. Every device in the sample is inspected and either accepted or rejected. It is desired to have a description of the sample attributes.

*Example 5-3:* In the factory of a pharmaceutical company, areas are classified according to their state of cleanliness. To ensure that the areas are as clean as intended, samples are taken on different surfaces in the rooms and the numbers of germs counted. It is desired to use the samples for a monitoring program for the state of cleanliness.

*Common background for the examples:* In all the examples, one wants to describe some data and, based on the data, set some kind of limits.

## 5.2 Distributions

Distributions are mathematical functions that fulfill specific criteria. Some of the distributions are very well described mathematically and have some nice properties. Practically, distributions are useful for describing different kinds of data, for calculating confidence intervals, setting limits, and modeling dependencies. They can also be used in hypothesis testing. Some distributions are only defined for non-negative integer numbers (0, 1, 2, ...) and may only be defined for a finite number of values. Such distributions are known as *discrete distributions.* Other distributions are defined for all non-negative real values or for all real values. These distributions are often referred to as *continuous distributions.* The name of a distribution, e.g., the normal distribution, the binomial distribution, is really not a name for *one* specific distribution but a whole class of distributions that all have some special characteristics. For example, there are many binomial distributions, but they are all defined on a finite number of integer values; they are all described by their probability parameter $p$, etc. Generally, the family of distributions has some common characteristics and then some parameters that defines exactly which distribution one is dealing with. For instance, the binomial distribution has the probability parameter and the count parameter. Similarly, the normal distribution has the mean and the variance parameters.

***5.2.1 Normal Distribution*** The normal distribution is one of the most well-known distributions. It is characterized by its mean $\mu$ and its variance $\sigma^2$. The normal distribution is sometimes referred to as the bell curve since its shape resembles a bell. The shape, however, depends on the values of the mean and variance (see Fig. 9). The normal distribution is a continuous distribution defined on the entire real axis. It is often used for describing measurements such as length, height, and weight. There are many nice assets to the normal distribution; e.g., if two normal distributions are "added" (folded), the new distribution is again a normal distribution. One of the most famous and useful assets for the normal distribution is the central limit theorem, which states that if $X_1, X_2, X_3, X_4, X_5, \ldots$ are all independent stochastic variables following a distribution with finite mean $\mu$ and finite variance $\sigma^2 > 0$, then the average $\bar{X}_n = \frac{1}{n}\sum_{i=1}^{n} X_i$ will approximately follow a normal distribution with mean $\mu$ and variance $\sigma^2/n$. For practical purposes, this means that if a sample is taken and the average calculated, then the average will behave as if it came from a normal

***FIGURE 9*** *Normal distributions with mean 0 and variance 1, mean 9 and variance 1.5, and mean 5 and variance 9.*

distribution, even though the distribution that the different observations in the sample stem from is not a normal distribution. For example, if "samples" each of 6 tosses with a fair dice are gathered, then the average of the samples will follow a normal distribution with mean 3.5. This property is very useful for setting limits or making control charts.

***5.2.2 Log-Normal Distribution*** The log-normal distribution is right-skewed – it has a long tail to the right – and is defined for all non-negative values (Fig. 10). If data follow a log-normal distribution, the natural logarithm of the data follows a normal distribution. So if one has data that are continuous and positive but skewed, then taking the natural logarithm of them might make them follow a normal distribution. It is then possible to use all the properties of and tools for the normal distribution and then transform any estimates back to the natural scale.

***FIGURE 10*** *Log-normal distribution with mean 0 and variance 1.*

***5.2.3 Binomial Distribution*** The binomial distribution is defined for two values, e.g., 0 and 1, heads and tails, and go or no-go. It can be used for describing the number of heads in $n$ coin tosses or the number of rejected items in a batch. It is described by the probability parameter $p$ and the "count" parameter $n$. $n$ is the number of coin tosses or the number of items in a batch, and $p$ can be thought of as the probability of heads in coin toss. Then the probability of tails is of course $1 - p$. The mean in a binomial distribution is $np$ and the variance is $np(1 - p)$.

***5.2.4 Poisson Distribution*** The Poisson distribution is defined for all non-negative integer values, i.e., 0, 1, 2, . . . . It can be used for describing rare events in a large population, e.g., the number of complaints on a specific product in the population of sold items of that product.

***5.2.5 Other Distributions*** Some distributions are used in hypothesis testing, e.g., the $t$-distribution, the $F$-distribution, and the $\chi^2$-distribution. All these distributions have a scale parameter denoted as the "degrees of freedom," which determines their shape. The $F$-distribution actually has two sets of degrees of freedom. There are many other distributions that are of interest. For a thorough introduction to these, refer to [2].

## 5.3 Examples Continued

*Example 5-1:* The average and standard deviation of the lengths is calculated and a histogram made to see if it is reasonable to assume that the measurements follow a normal distribution. If that is the case, a tolerance interval for the lengths can be calculated and stated in the description. This will give the receiver of the components an idea of how much the components vary in lengths.

*Example 5-2:* The number of rejects in the samples will follow a binomial distribution with count parameter, the size of the sample, and an unknown probability of rejects. However, an estimate of the probability of rejects could be made from the sample.

*Example 5-3:* The count of germs in a room will be a non-negative integer value, and for the very clean areas, there will probably be a lot of times where there are no germs at all. Therefore, a Poisson distribution might be suitable to describe data, but other distributions could be useful as well (log-normal or negative binomial). To assess fit, a histogram of data should be made along with fits of the different distributions. Once a distribution has been chosen, alert limits for the number of germs could be established based on the percentiles in that distribution.

# 6 SAMPLING

## 6.1 Examples

*Example 6-1:* From a batch of a pharmaceutical finished product, samples are taken during the production process and analyzed for the content of the active

ingredient. From the samples, both the average content and the variation of the content throughout the batch are estimated. Both need to comply with specification limits.

*Example 6-2:* A supplier delivers devices for inclusion in a manufacturer's product. The manufacturer tests the quality of the delivered batches by conducting a destructive test on a number of samples from each batch. The manufacturer and the supplier have agreed on a specific maximum percentage of defective devices. When delivery is stable, the manufacturer wishes to spend as few devices as possible on testing. However, if problems are seen, the manufacturer wishes to intensify the tests. To ensure agreement, both parties wish to agree beforehand on the amount of testing and acceptance criteria.

*Example 6-3:* Following a change in a production process, a process validation is conducted. The change was done in order to raise a parameter from its former to a new level. The process validation has the goal to show that the new level is obtained, within specified limits.

*Common background for the examples:* In all examples, a sample from a batch is supposed to represent the whole batch. From test results for the sample, it is estimated what is probable as test results for the whole batch, had it been tested in its entirety. The choice of the sample size is a compromise between obtaining sufficient knowledge to ensure a minimum quality level and minimizing testing costs.

## 6.2 Introduction of the Tool

When a sample is drawn from a batch, statistics such as the mean, variance, or percentage of defects will not be exactly the same in the sample as in the entire batch. But from the sample, one can estimate the corresponding statistics for the entire batch. The estimates for the entire batch come with an uncertainty that depends on the type and distribution of the data and on the sample size. Typically, one can reduce uncertainty by drawing larger samples.

## 6.3 Practical Details

***6.3.1 Point Estimates*** The best estimates for the mean and standard deviation in a batch are the average and standard deviation in a sample drawn from the batch. Typically, specification limits are directly defined as limits for the average and standard deviation of a sample of a certain size, allowing for simple comparison once the results for the sample are known.

***6.3.2 Confidence intervals*** If one draws a new sample from a batch, the mean and the standard deviation will very likely not be exactly the same as in the first sample. However, the larger the sample, the closer to each other will the estimates typically be (percentage estimates from small samples in large populations are an exception). Depending on sample size, one can calculate a confidence interval for the point estimate. A 95% confidence interval contains the true value of the parameter of interest parameter with 95% probability. That is, if you calculate a 95% confidence interval for an average from a sample, the true average for the entire batch is with 95%

probability within the confidence interval. Thus, the interval tells you how precise your estimate is. You can compare the interval to pre-defined limits that are based on requirements to the batch and thus conclude whether the quality of the batch is sufficient for the requirements. If your interval is very broad, the information you obtained from the sample may not be useful. You may need to increase the sample size to obtain more precise information.

***6.3.3 Sample Size Calculations*** Typically, one starts out with requirements to the batch, and an expectation as to what the quality will be. In this situation, one can calculate the appropriate sample size that will ensure a confidence interval that stays clear of the limit for acceptable quality for the batch, if indeed the batch quality is as expected (see, e.g., [3]). The closer the expected quality is to the worst acceptable quality, the larger a sample one will need in order to discriminate between the two. The methods for sample size calculation in this case are the same as those used by biostatisticians to determine the sample size in clinical trials (see, e.g., [4]).

***6.3.4 Acceptance Sampling*** There are ISO standards describing procedures for inspection sampling that can be helpful to contractually define the amount of testing and acceptance criteria [5,6]. The parties agree to an acceptable quality level (AQL), i.e., an average of a continuous measurement, or a percentage of non-conforming items per batch, which is the worst acceptable level. The supplier is asked to provide an average quality better than AQL. Depending on the batch size, the standard then prescribes a sample size and an acceptance number, i.e., for go/no-go measurements a maximum number of non-conforming items in the sample necessary to accept the batch, and for continuous measurements a limit for an acceptance number that is calculated from average and standard deviation in the sample, and the specification limits. The standards also prescribe procedures for relaxing and tightening the inspection, depending on the history of quality in earlier deliveries, and schemes for actually skipping batches for inspection if one is confident in the quality.

## 6.4 Traps

***6.4.1 Representativeness*** For the described procedures to work, it is necessary that the sample is representative. That is, all variation that occurs in the batch should also occur in the sample. It is therefore not advisable to collect all samples from one time spot during production. Sampling at fixed time intervals can also upset representativeness, if systematic variation occurs in the periods between samples – e.g., if high values of content occur just before a container of supply is changed, but samples are drawn systematically just after the change.

***6.4.2 Systematic Variation in a Limited Part of the Batch*** An underlying assumption for sampling is that the batches are homogenous. If, e.g., a disturbance causes highly diverging values in a limited part of the batch, a sample is likely not to pick up on it. Either none of the affected items ends up in the sample, or if it does, the

sample values may only be slightly affected, as the problematic part of the batch is small as compared to the rest.

***6.4.3 Outliers*** When drawing a sample, you may end up with one or few data points that look inconsistent with the remainder of the sample. Such data can have a strong influence on the point estimates. If there is actually something wrong with these data points, e.g., a measurement error or recording error, they can render the point estimates useless. In this case it may be wise not to include the outliers in the estimate calculation. There are outlier tests that help you decide whether one or several strange-looking data points actually are likely to stem from the same distribution as the remainder of the sample (see, e.g., [7]). But beware: When excluding outliers, you risk excluding data that actually do represent your process, and thereby heavily underestimating variation. Furthermore, often it is the different-looking data points that can put you on track of a process property that you did not know about, and thereby can be highly valuable sources of knowledge. Don't toss them away too easily.

## 6.5 Examples Continued

*Example 6-1:* Sample size and limits for the average and standard deviation in the sample are chosen such that the confidence intervals for the mean and standard deviation in the entire batch are within reasonable limits. Sample size and limits for the results from the samples are documented in the specification.

*Example 6-2:* In this example, the ISO standards for sampling procedures for attributes can be employed with advantage.

*Example 6-3:* Sample size calculations are conducted to ensure proper documentation of the level change, assuming that the level indeed has changed to the desired level.

# 7 STATISTICAL PROCESS CONTROL (SPC)

## 7.1 Examples

*Example 7-1:* In every analysis run of an HPLC-analysis, a control sample is measured. The purpose of the control sample is to verify that the analysis is performing as intended; i.e., there are no abrupt changes in the level, drift over time, or increase in variation. Furthermore, it is desired to use the control sample to follow the analysis over time.

*Example 7-2:* During production of a medical device, one of the parts for the device is tested in a strength test. From every produced batch of the part, a sample of six parts is taken and tested using the strength test. Both the level of the strength and the variation should be controlled.

*Example 7-3:* During production of switches for a medical device, samples of switches are collected on a regular basis, and the number of non-conforming

switches is determined. The purpose of the sampling is to check whether the production of switches is in control, which means the number of non-conforming switches must not increase.

*Common background for the examples:* In all the above examples, it is desired to follow a process (analysis, production line) over time and control that it is performing as intended, to react if the process is out of control, and not to react to random fluctuations as long as the process is in control. In order to achieve that, samples are periodically drawn from the process and measured. In Examples 7-1 and 7-2 the control measurements are continuous, whereas in Example 7-3 the control measurement is a go/no-go determination.

## 7.2 Introduction of the Tool

Statistical process control is a tool to understand and control processes. Generally, all work can be seen as a system of interconnected processes and all processes are subject to variation. The latter can be separated into two parts: variation due to special causes and variation due to common causes, or random variation. Common causes are causes that cannot be removed, e.g., day-to-day variation or operator-to-operator variation – they are inherent to the system. Special causes have a large effect on the system and are "abnormal" or exceptions. One specific operator or machine can cause them, or they can happen on one specific weekday. Sometimes, it can be hard to determine if a cause is special or common; e.g., operator-to-operator variation is a common cause, but if one operator is especially good or bad, that operator will be a special cause. To obtain control and stability of a process, the variation should be reduced as much as possible. In order to do that, one must know and understand the process and its variation. Ishikawa diagrams, process flow charts, and Pareto analyses can all be useful in the process understanding phase. Once knowledge of the process is obtained, the special causes of variation should be removed. Then the common causes should be reduced as much as possible. A process that is only subject to variation due to common causes is said to be in statistical control. A process that is in control has no drift and no sudden shifts in level. In Fig. 11 a process is shown, which is *in control*. Figure 12 shows a process that is *out of control*.

When the state of statistical control is reached, control charts can be constructed and used to maintain the state of control. There are many different kinds of control

***FIGURE 11*** *Process in statistical control.*

***FIGURE 12*** *Process which has drifted and thus is out of control.*

charts; in the following a few of those will be briefly described. For a more thorough description, see [1].

## 7.3 Types of Control Charts

***7.3.1 Shewhart Charts*** Shewhart charts are charts for normally distributed data. If, as in Example 7.2, samples of several items are drawn, both charts for the level (mean) and variation (standard deviation/range) can be constructed. The mean chart ($\bar{x}$-chart) is constructed using the average ($\bar{x}$) as the mid-level and $\bar{x} \pm 3\times$(standard deviation of the mean estimate) as the lower and upper limits of the chart. If data are truly normally distributed, 99.73% of the observations will be within the upper and lower limits. Thus it is very unlikely that an observation falls outside the limits by chance – unless the process has changed. The chart for variation – the $s$-chart – is constructed in a similar way with $\bar{s}/c_4$ as the centerline and $\bar{s} \times B_4$ and $\bar{s} \times B_3$ as the upper and lower limits. $c_4$, $B_3$, and $B_4$ are all constants that depend on the size of the sample [1]. An example of a $\bar{x}$- and $s$-chart is shown in Fig. 13. In order to determine limits, data from at least 20 samples should be available. Based on these, the limits can be calculated and the chart drawn. The 20 samples must all be from a period where the process is in control. When the charts have been constructed every time a sample is taken, $\bar{x}$ and s should be calculated based on the sample and plotted in the chart. If both of them are within the limits, the process is in control. Besides the limits, seven run rules exist to warn if the process is drifting, variation is increasing, etc. The run rules

***FIGURE 13*** *x-bar chart and s-chart for a process in control.*

are designed to increase the charts' sensitivity toward specific kinds of expected changes. It is not advisable to apply all the run rules to the charts since that will sharply increase the number of false alarms.

***7.3.2 p-Charts*** When control measurements are in the form of go/no-go, the control chart needs to reflect this. If the measurements are recorded as fraction non-conforming or the number of non-conformities in the sample, $p$-charts or $np$-charts are used respectively. Both of these are based on the binomial distribution. The $p$-chart monitors the fraction of non-conforming items. It consist of a centerline $\bar{p}$ and a lower and upper limit often calculated as $3\times$(standard deviation of $\bar{p}$). $\bar{p}$ is the average fraction of non-conforming items. The process is in control as long as $\bar{p}$ for the samples are within the limits. $np$-charts are constructed in the same way, except that the centerline is given as $n\times\bar{p}$, and the limits are $3\times$(standard deviation of $n\times\bar{p}$). The advantage of the $np$-chart compared to the $p$-chart is that if the sample size is always the same, one plots the number of non-conforming items directly without further calculations.

***7.3.3 Other Charts*** The charts discussed above can be modified in the sense that the limits can be changed to cover another percentage of the distribution. If it is critical that the process is stable, one could use $2\times$(standard deviation of $\bar{x}$) as limits. This would cause more alarms but make the system more sensitive to a change in the process. In the same way if a process change is not critical and the workload caused by alarms is high, one could use wider limits than $3\times$(standard deviation of $\bar{x}$).

If data are not very well described by a normal distribution and there are plenty of data, or knowledge from similar processes exists, one could use the empirical distribution – the exact distribution created by the actual data – as the basis for the chart. The limits could then be chosen as percentiles from the distribution. For example, the 1 and 99 percentiles could be used as limits.

## 7.4 Traps

***7.4.1 Non-Normality*** If Shewhart charts are used, it must be investigated if the measurements follow a normal distribution. If the distribution heavily differs from a normal distribution, the limits could be erroneous and cause too many or too few alarms depending on the real distribution. In this case, one could try to transform data into something which is normally distributed. The natural logarithm is often useful as a function for transformation.

***7.4.2 Overinterpreting Alarms*** If 99% limits are used, then in theory one out of hundred observations should fall outside the limits. So alarms can appear without the process having changed.

***7.4.3 Changing Process*** The limits should be evaluated once in a while. If the process has not changed, new limits could be calculated on the basis of all data, reducing the uncertainty on the limits. If there have been no alarms at all for a long

time of operations, it could be a sign that the process has actually improved. If a shift in the process happens, the limits should be recalculated based on the new process level.

### 7.5 Outlook

Many other control charts exist besides the Shewhart and the $p$-charts (see, e.g., [1]). CUSUM charts model sums of binomial variables describing some characteristic of the process. There are also charts for moving averages, exponentially moving averages, etc. It is also possible to do multi-dimensional SPC to monitor several correlated process variables in the same chart, especially if data are normally distributed. Finally, if other limits exist than those set in the control chart, e.g., tolerance limits, process performance can be assessed by relating these external limits to the process-inherent limits derived for the charts. Such fractions are called capability indexes. A capability index is a measure of the amount of space the process has to "move within" without exceeding the external limits. If there is a lot of room for the process within the limits (the capability index is large), the process can be out of statistical control and still be within the limits. If the capability index is small, the process is close to at least one of the external limits, and scrap is produced as soon as a slight change in process level or variation occurs.

### 7.6 Examples Continued

*Example 7-1*: A control chart for individual measurements could be constructed for the measurements of the control sample. It is also possible to construct a chart following the variation of the measurements, but that has to be based on observation from more than one analysis run. If a change in the process appears, one needs to consider if it is the control sample which has changed (a drift could be due to degradation of the sample) or if it is the HPLC-system which has changed.

*Example 7-2:* If the strength measurements follow a normal distribution, Shewhart control charts can be made for both $\bar{x}$ and $s$. The $\bar{x}$-chart controls the level of the process and the $s$-chart controls the variation. It would be advisable to apply some of the run rules. These should be chosen to reflect what is most likely to happen to the process or what is most critical to the process.

*Example 7-3:* An $np$-chart could be constructed monitoring the number of non-conforming switches in the sample. If the sample is large and the number of non-conforming items is very small, a control chart based on the Poisson distribution may be more suitable.

## 8 HYPOTHESIS TESTING

### 8.1 Examples

*Example 8-1:* A pharmaceutical laboratory wants to compare two analytical methods. It is believed that one of the methods is better than the other, and

it is desired to verify that belief. A number of samples are analyzed using both methods. Data are continuous and can be described by normal distributions.

*Example 8-2:* A pharmaceutical company is considering two types of tanks for their fermentation process. It is believed that the yield from one tank is higher than from the other, but the company would like to investigate this before deciding which tank to use.

*Common background for the examples:* In both examples one wants to compare two things, and one has a belief that one of the things is better than the other.

## 8.2 Introduction to the Tool

Statistical testing is reminiscent of solving an advanced sudoku puzzle. If you cannot determine directly which of two numbers goes into a specific field, you choose one as hypothesis and follow the puzzle through from there. If a contradiction occurs, the other number must have been the correct one. If no contradiction occurs, the number first chosen is possible – but you do not know whether the second number would have led to a solution as well. If the sudoku was constructed according to the rules, there should only be one possible solution, but in real life that is not always the case.

Also in statistical testing, you choose a hypothesis and see whether it leads to a contradiction. You choose a null hypothesis that is actually the opposite of what you want to show. The hypothesis you are really interested in is referred to as the alternative hypothesis. In the case of the two analysis methods, the null hypothesis is that the two analysis methods are equally good. Hypotheses must be formulated in mathematical terms, and they concern the population parameters of the distribution (s) describing the actual data. For example, it may make sense to translate "method A is better than B" into "method A has a smaller variance than B," or "the measured level of some reference standard is closer to its certified level when measured with method A than with B." The population parameters are unknown, but they can be estimated from the actual data (see 6). Using the distribution of data and the hypothesis, a test statistic can be calculated. When the null hypothesis is true, the distribution of the test statistics is known, and it can be determined how likely it is to observe something at least as extreme as the test statistic. The notion "extreme" means further out in the tail(s) of the distribution of the test-statistic (see Fig. 14). If the chance of observing something at least as extreme is small, the null hypothesis is rejected. If the chance of observing something at least as extreme as the test statistic is large, the null hypothesis is accepted. The chance of observing something at least as extreme as the test statistic is often referred to as the *p-value* or the test probability. The idea behind this setup is that the distribution of the test statistic is known when the null hypothesis is true. If the observed test statistic – based on the actual data – is extreme (far out in tail of its distribution), there are two possibilities: Either one has by chance observed a very unlikely test statistic, *or* the null hypothesis is wrong. As the first possibility by definition is very unlikely, the conclusion is that the null hypothesis is wrong.

***FIGURE 14*** *The hatched area is in the right tail of the distribution.*

## 8.3 Practical Details

***8.3.1 Significance Level*** How small should the chance of observing something at least as extreme as the test statistic be in order to reject the null hypothesis? That is determined by the significance level. Often a significance level of 5% or 1% is used. If the chance of observing something at least as extreme as the test statistic is less than the significance level, the hypothesis is rejected.

***8.3.2 Type I Error*** If the null hypothesis is really true and a significance level of 5% is used, then in 1 out of 20 times, one will get a $p$-value that is less than 5% and thus reject the null hypothesis even though it is true. This type of error is known as the type I error. This is similar to a criminal court where the accused is considered innocent until the opposite is proved. In the statistical case, the null hypothesis is considered true until proven wrong. If it is very important that the null hypothesis is not rejected when it could be true, a low significance level should be chosen. If the null hypothesis is accepted, it is not the same as having shown that it is true. Again this is similar to the court case: Even if an accused is not convicted that is not the same has having proved him or her innocent. What one can conclude is that there is no evidence in the data to reject the null hypothesis.

***8.3.3 Type II Error*** The type II error represents the risk of accepting the null hypothesis when it is in fact wrong. The type II error is often denoted $\beta$ ($0 \leq \beta \leq 1$). $1 - \beta$ is known as the power, which is the chance of actually rejecting the null hypothesis when the alternative hypothesis is true. The power cannot be controlled for a given sample size but depends on the true parameters. The power is often used when one wants to determine the sample size in an experiment or clinical trial [1]. Often $\beta$ is chosen to be 10% or 20%.

***8.3.4 Sample Size*** It can be very important to assess the right sample size before an experiment is run. If the sample size is too small, the experiment will be inconclusive. On the other hand, it is often quite costly to do an experiment; therefore, it is desirable to keep the sample size as small as possible (see 6).

***8.3.5 One- and Two-Sided Tests*** In a two-sided test, both tails of the distribution of the test statistic are used. If the null hypothesis is $a = b$, and the alternative hypothesis is $a \neq b$, then this is a two-sided test since one is not assuming whether $a$ is larger than $b$ or smaller than $b$. In the corresponding one-sided test, the null hypothesis is still $a = b$, but the alternative hypothesis is $a \leq b$ or $a \geq b$. In either of these cases one would only be using one tail of the distribution of the test statistic. In the case of the two fermentation tanks that would mean testing the hypothesis "The two tanks give the same yield" against the alternative "Tank B gives higher yield than tank A." In this case, if B gave a lower yield than A, that would not be considered extreme.

***8.3.6 Equivalence Test*** In Example 8-1 if the laboratory really wanted to show that the two methods were equal, they should use an equivalence test. The idea in an equivalence test is to show that the difference between the parameters describing the two groups of interest, e.g., the level of the two methods, is smaller than some predefined value $K$. The value $K$ is chosen in advance of the test and is the largest acceptable difference between the two parameters. One finds the estimated difference between the two and, e.g., the 90% confidence interval for the difference. If the confidence interval is within $[-K, K]$, one has shown that the nominal difference between the two parameters of interest is less than $K$.

## 8.4 Different Tests

Statistical tests are often referred to by the name of the distribution of the test statistic. So a $t$-test is a test where the test statistic follows a $t$-distribution. Furthermore, some distributions are also described by a parameter called the "degrees of freedom" [2].

***8.4.1 t-test:*** The $t$-test is a test comparing the means of two groups, where data can be described by a normal distribution. It is possible to make a $t$-test either assuming that the variance is the same in the two groups, or assuming it differs. The difference between the two situations is the variance estimate and the degrees of freedom. If a $t$-distribution has a high number of degrees of freedom, it is very similar to a normal distribution with mean 0 and variance 1.

***8.4.2 F-test:*** The $F$-test is typically for comparing two variances. In an adaptation, it can also be used for an overall assessment of whether the means in several groups of normally distributed data are different or all equal. The $F$-test has two degrees of freedom, relating to the two variances.

***8.4.3 Chi-square test:*** The chi-square distribution is used in many different kinds of tests. One of the most well-known applications is the likelihood ratio test, which compares two statistical models, where one is nested in the other. The chi-square distribution is also referred to by its degrees of freedom.

***8.4.4 Non-parametric tests:*** If data cannot be described by any known distribution, a number of "distribution-free" tests exist [2]. These tests may not

yield as much knowledge as a parametric test, but if the assumptions for a parametric test are not fulfilled, a non-parametric test may be more adequate.

### 8.5 Examples Continued

*Example 8-1:* The two methods could be compared using a *t*-test. The null-hypothesis would be that there is no difference between the methods.

*Example 8-2:* An experiment should be designed to investigate if there is difference in yields between the two types of tanks and then the null hypothesis of no difference should be tested.

## 9 COMPARING GROUPS: ANOVA

### 9.1 Examples

*Example 9-1:* Two machines are producing components for a pharmaceutical device. It is suspected that the lengths of the components differ for the two machines, and an investigation is started to determine if there is a difference between components from the two machines. Data from both machines are collected for 10 days of production.

*Example 9-2:* A step in a pharmaceutical process has been optimized. Management would like to know if the optimized process has an effect on the strength of the product.

*Example 9-3:* In a QC laboratory an HPLC-analysis is routinely performed as a quality control of a given product. The analysis is performed on three HPLC-systems. One wants to know if differences in results stem from the use of different HPLC-systems, different technicians, or possibly both.

*Common background for the examples:* In the examples given above, several features are the same. It is desired to compare results from at least two groups (two machines, pre- and post-optimizations, three HPLC-systems). All results are measured on a continuous scale, and finally, it is desired to find out if there is a difference between the groups.

### 9.2 Introduction of the Tool

ANOVA is short for ANalysis Of VAriance. The term is used for statistical analyses where data are assumed to follow a normal distribution, observations are independent, and explanatory variables are categorical.

### 9.3 Practical Details

***9.3.1 Two Groups of Normally Distributed Data*** In the following it is assumed that data are normally distributed. We want to compare two groups of measurements to determine if they are different. The two groups of data stem from two normal distributions. Two normal distributions can differ in several ways: They can

have both different means and different variances, they can have the same variance but different means, they can have equal means and different variances, and finally both means and variances can be equal, meaning that the distributions are the same.

***9.3.2 Comparing Means*** Assume that the variances in the two groups are the same but unknown and that the means are unknown as well. We want to know if the means are different. Therefore, we want to test the null hypothesis that the means are equal against the alternative hypothesis that the means are different. Under the null hypothesis, all data stem from the same normal distribution. Therefore, a way to test the null hypothesis is to measure how far the difference in group means is from zero, taking into account the variance of the difference. This is done by constructing the t-statistic:

$$T_0 = \frac{\bar{x}_1 - \bar{x}_2}{\text{Std. dev.}\,(\bar{x}_1 - \bar{x}_2)}$$

Note that the numerator is the estimated difference between the two group means and the denominator is the estimated standard deviation of the numerator. When the variances are the same in the two groups, this statistic is known to follow a $t$-distribution with $n-2$ degrees of freedom where $n$ is the total number of observations. The hypothesis is rejected, if the chance of getting something more extreme (further away from zero) than $T_0$ is less than 5%, when the significance level is 5%. It is also possible to compare the two means by a t-statistic when the variances in the two groups are not the same, but then the degrees of freedom are different [8].

***9.3.3 Comparing Two Variances*** It is also possible to test if the two variances are the same. The test is performed under the assumption that the means are different. Here the null hypothesis is that the ratio between the two variances is 1. A test statistic is constructed, which follows an $F$-distribution with $(n_1 - 1,\ n_2 - 1)$ degrees of freedom where $n_1$ is the number of observations in group 1 and $n_2$ is the number of observations in group 2. If the test probability ($p$-value) is larger then the chosen significance level (often 5%) the null hypothesis cannot be rejected. This is NOT the same as having shown that the hypothesis is true; e.g., the variances are the same. If one really wants to show that two parameters are the same, one should use an equivalence test [9]. However, for modeling purposes, when the null hypothesis cannot be rejected, the non-significant effect is removed. In Example 9-1, that means one would usually start by performing the test for equal variances, and if the hypothesis is not rejected, it is assumed that the variances are equal, and one proceeds with the test for equal means.

***9.3.4 Comparing Several Groups*** In the same way as for two groups, it is possible to test if several group means are the same. This is done using an F-statistic (but different than the one used for comparing two variances). The test statistic is a measure of how big the variance is within the groups compared to how big the variance is between the groups as shown in Figs. 15 and 16.

***FIGURE 15*** *There is small variation between the groups compared to the variation within the groups.*

Figure 15 shows the case where there is large variance within the groups compared to the variance between the groups. In this case it is not possible to reject the null hypothesis. In other words, there is no evidence in the data to show that the groups are different. In Fig. 16 there is little variance within the groups compared to the variance between the groups. In this case the null hypothesis of equal means in the groups would be rejected, and it is concluded that the groups are different in the sense that their means are different. Again it is assumed that the variances are the same in all the groups. A number of tests exist for testing this assumption ([10], p.227). When there are several groups, it might also be relevant to make pairwise comparisons. This is done as described under comparing two groups. However, if many pairwise comparisons are made, one should consider using a correction for multiple testing [11].

***FIGURE 16*** *There is large variation between the groups compared to the variation within the groups.*

***9.3.5 Group as Random Effect*** Consider machine 1 from Example 9-1. One might want to model the variation between days. In this case it is not the levels for the different days that are of interest since these are just a random sample of all the days, where data might have been collected. Thus we would like to model the differences between days as variation and determine how large the day-to-day variation is and how large the within-day variation is. It is thus assumed that all measurements are normally distributed with the same mean and with a variance that consists of a day-to-day component and a within-day component. The estimation of the components is very similar to the one under the section "Comparing Several Groups." When the number of observations on each day is not the same, the calculation of degrees of freedom is not straightforward, but it can be handled by most statistical software programs.

***9.3.6 Two-Way ANOVA*** In Example 9-3, there are two explanatory grouped variables, and it is desired to investigate their effect on the measurements. This can be analyzed in a two-way ANOVA. Data are again assumed to follow a normal distribution with the same variance. In the interaction effect model, the mean is assumed to be different for each combination of the two factors (technician and HPLC-system) in an "unsystematic" way (see Table 1).

One can start by making an overall $F$-test of whether the mean depends on any factors at all. If the test is rejected, one can proceed in the following way. First, the interaction effect is tested.

If the interaction effect is non-significant, the model can be reduced to a two-way additive model. In this model the mean still depends on the two factors but now in a systematic way, in the sense that a shift from one level in factor 1 to another level influences the mean in the same way for all levels of factor 2. From this model the effect of either factor 1 or factor 2 can be tested, and if that hypothesis is accepted, the hypothesis of no effect of the remaining factor can be tested (see Fig. 17). If one of these hypotheses is accepted, then the other one can be tested afterwards. If all the hypotheses are accepted, it means that there is no evidence in data to support the hypothesis of any differences between the two factors. This conclusion could also have been reached if one had started out with the overall $F$-test. A little care should be exercised though in using this approach since, sometimes, testing the two different ways might not give the same result. In order to test the hypothesis of no interaction between the two factors, there should be more than one observation for each of the

**TABLE 1 Interaction Effects**

| No Interaction Effect | | | Interaction Effect | | |
|---|---|---|---|---|---|
| | HPLC 1 | HPLC 2 | | HPLC 1 | HPLC 2 |
| Tech. 1 | 10 | 20 | Tech. 1 | ***30*** | 20 |
| Tech. 2 | 15 | 25 | Tech. 2 | 15 | 25 |
| Tech. 3 | 8 | 18 | Tech. 3 | 8 | 18 |
| Tech. 4 | 12 | 22 | Tech. 4 | 12 | 22 |

***FIGURE 17*** *Possible ways to test in a two-factor ANOVA.*

combinations of the levels of factor 1 and factor 2. If there is only one observation for each combination, the starting model is the additive model.

***9.3.7 Several Factors*** ANOVA with three or more factors can be handled similarly to the one described for a two-factor ANOVA. It is not always relevant to test the highest order interaction or it might not be possible due to the amount of data needed.

***9.3.8 Model Assumptions*** In all the ANOVA models, it is assumed that data follow a normal distribution and that the observations are independent. These assumptions should be verified by model checking, e.g., histograms and residual plots.

## 9.4 Examples Continued

*Example 9-1:* One can start out by comparing the variances from the two machines using an $F$-test. If the $F$-test is accepted, one can proceed comparing the two means as described above. If the difference is statistically significant, one can evaluate if the difference is also practically significant. This is not always the case. If there are more than one observation from the machines on each day, one could also determine the day-to-day variation and the within-day variation for each machine.

*Example 9-2:* Measurements of the strength before and after the process optimization could be compared. Both the variation and the mean of the strength should be compared.

*Example 9-3:* The effect of HPLC-system and technician could be assessed using a two-way ANOVA. If each technician on each HPLC-system makes several measurements, it is possible to investigate if there is an interaction effect between system and technician. If there is no interaction, it means that a shift from one HPLC-system to another influences the mean in the same way for all technicians. From that model the hypothesis of no difference between technicians can be tested, or the hypothesis of no difference between HPLC-systems.

# 10 MODELING LINEAR DEPENDENCE: LINEAR REGRESSION

## 10.1 Examples

*Example 10-1:* In a stability study, the concentration of a degradation product raises over time at a constant rate. First, one needs to determine the rate. Next, one needs to make sure that product released at the release limit will, with a certain probability, not exceed the shelf life limit at the end of shelf life.

*Example 10-2:* In an assay, one measures concentration of a certain molecule. One cannot determine concentration directly, but the degree of opacity which in this case is known to depend linearly on the concentration. One then analyzes the test samples together with a number of reference samples of known concentration. On the basis of the degrees of opacity of all samples, and the known concentrations of the reference samples, one can estimate the concentrations in the test samples.

*Example 10-3:* A yield depends on pressure and temperature in the process. If the pressure is kept constant, yield depends linearly on temperature (within a certain temperature range) and vice versa. However, changing both at the same time can have a different effect on yield than the sum of the effect of changing each of them from the starting point.

*Common background for the examples:* A dependent variable $y$ depends linearly on a continuous independent variable, or regressor, $x$. In all cases, one wants to model the dependence. The model is then used for different purposes: In the stability example, the analytical response $y$ is predicted for a given time point $x$. In the assay example, the concentration $x$ is estimated for a given response $y$. In the yield example, the dependent variable depends on two different regressors at the same time.

## 10.2 Introduction of the Tool

***10.2.1 Simple Regression Model*** For pairs of independent variables $y_i$ and regressors $x_i$, the model equation is $y_i = a + bx_i + e_i$, where the error term $e_i$ describes the difference between the predicted value $\hat{y}_i = a + bx_i$ and the data value $y_i$ for each $x_i$ (see Fig. 18). The parameters $a$ and $b$ describe the intercept

***FIGURE 18*** *Simple regression.*

and the slope of the regression line, respectively. Collectively, they are termed regression coefficients. The error terms $e_i$ are assumed to be independent and to follow a normal distribution.

***10.2.2 Multiple Regression Model*** A dependent variable can depend on several regressors, as in Example 10-3. The full model equation for two regressors $x$ and $z$ is

$$y_i = a + b \cdot x_i + c \cdot z_i + d \cdot x_i \cdot z_i + e_i$$

where $d$ is the parameter of the interaction term. One can test by means of a $t$-test whether $d$ is significantly different from 0. In this case, one says that the variables $x$ and $z$ interact. If two continuous variables do not interact, the graph for the model shows a plane. If they do interact, the plane is twisted (see Fig. 19). Computationally, any number of variables can be included in a model.

## 10.3 Practical Details

***10.3.1 Estimating the Regression Coefficients*** There are different methods to estimate the regression coefficients for a given dataset. The most common method is the method of least squares, which minimizes the sum of squared error terms. Least square estimates for $a$ and $b$ can be calculated using a closed formula (see, e.g., [2], p. 475). Other methods of estimation exist, e.g., the maximum likelihood method ([2], p. 293), which in many cases results in the same estimates as least squares, or Bayesian methods ([2], p. B-28). For the latter, there are usually no closed formulas for the estimates of the regression coefficients, but they are obtained iteratively.

***10.3.2 Checking the Assumption of Independent, Normally Distributed Error Terms*** Graphical methods are very helpful here. A histogram of the error

***FIGURE 19*** *Multiple regression with interaction.*

terms and a scatter plot of the error terms vs. the regressor(s) can show whether any systematic variation is left in the error terms or whether the error terms follow, e.g., a highly skewed distribution. In this case, tests in the model will not be valid.

***10.3.3 Testing for Overall Goodness of Fit*** *R*-square is a commonly used, but controversial ([2], p. 510), method to assess overall goodness of fit. It is a measure of how much of the variation in the data is explained by the model. It is computed as 1 minus the ratio of the error sum of squares and the total sum of squares. It is a number between 0 and 1, with 1 indicating that the model perfectly fits the data. *R*-square can be misleading when used to compare different models for the same data. For example, it increases with increasing number of regressors in a multiple regression model, also if the newly included variables do not contribute to explaining the variation. The adjusted *R*-square is an attempt to remedy this weakness. It includes a penalty for the number of regressors.

***10.3.4 Testing for Individual Parameters*** In multiple regressions, models can easily become rather complicated. To keep it simple, one needs a method to point out those regressors and interactions in the model that explain a significant part of the variation in the dependent variable. All other possible regressors can be left out of the

model. To decide which regressors and interactions to include, one can use $t$-tests. The tests are conducted by constructing an ANOVA table. Typically, one starts with the full model including all regressors and all their interactions, or with all interactions up to a certain degree. As for the ANOVA, one conducts an $F$-test for the overall significance of the model, and $t$-tests for the significance of individual parameters, starting with the higher order interactions.

***10.3.5 Confidence and Prediction Intervals*** Confidence intervals for the parameters result in an area around the regression line where each possible line within the area represents a model that would be consistent with the data. In simple regression, the area has a double trumpet shape; i.e., the uncertainty is greatest at the extremes of the data range (see Fig. 20). Prediction intervals show for each $x$ the range of $y$'s that would be consistent with the model. The prediction intervals are wider than the area defined by the parameter confidence intervals because they are based on both the model uncertainty, which is the basis for the confidence intervals, and the uncertainty associated with a single new observation.

## 10.4 Traps

***10.4.1 Extrapolation*** Extrapolating means using the regression outside the range of the observed data points. One assumes that the model derived from the observed data will also be useful in a different range. Caution should be exercised here, as many relations between measurable variables are far from linear when considering a wide range of values for the regressors. As no data are available to indicate the model fit in the extrapolated range, predictions can be highly misleading. See Fig. 21 for a dataset where a regression line estimated from the first seven observations would be very far from predicting the 20th observation correctly.

***FIGURE 20*** *Regression line with confidence limits for the line (closest to the regression line) and individual prediction limits.*

***FIGURE 21*** *Regression line which is not suitable for extrapolation.*

***10.4.2 Single Points with High Impact*** The further away from the average of $x$'s the $x$ value of a data point is, the larger is its impact on the slope of the regression line. A single data point with high uncertainty, if it has a very high or low $x$ value, can therefore seriously jeopardize the predictive value of a regression model (see Fig. 22). If you can plan where data are to be collected, consider placing many data points at the extremes of the range you want to cover, in order to minimize the uncertainty of the slope estimate.

***10.4.3 Non-Uniform Error Variance*** Regression models assume that the error variance is the same over the entire model. In many real-life situations, this is not the case. For example, the variance is often larger for higher dependent variable values. In

***FIGURE 22*** *Regression line highly influenced by one observation.*

***FIGURE 23*** *Linear relationship with non-uniform error variance.*

simple regression, such non-uniformity of the error variance can already be seen in a scatter plot of the data (see Fig. 23). For multiple regression models, one can detect it by plotting the error terms against the regressors, one by one. In the case where the variance is higher for higher values of a regressor, you can sometimes solve the issue by modeling the logarithms of the regressors and the dependent variable, rather than modeling the regressor and the dependent variable directly. When using this solution, we recommend you check whether indeed the residuals expose a more uniform error variance than in the original model.

***10.4.4 Multi-Collinear Regressors*** Multi-collinearity arises in multiple regression models if the regressors are not independent of each other; i.e., one of them is close to a linear combination of the others. In this case, the regression coefficients are very sensitive to the specific data and the model chosen, and can vary widely during the model building process. Worse, the prediction of values outside the dataset on which the model is built can be extremely poor (see Fig. 24). The most effective way to deal with multi-collinearity is to collect additional data that break the linear dependence between the regressors. Another option is to respecify the model such that the regressors become independent, e.g., by removing one regressor from the model or by using a suitable function of the original regressors instead. Also, specialized statistical procedures have been proposed, e.g., ridge regression (see [12]) and principal component regression (see [20], p. 353).

***10.4.5 Interpretation: Significant Relationship Does Not Imply Causality*** As with correlations, a significant relationship does not imply that the value of the regressor is actually the cause for the value of the dependent variable. Unlike for correlation, the regressor and dependent variables have different roles. If you exchange the roles in simple regression, you end up with a different estimated regression line (see Fig. 25). This effect occurs because you minimize the variance of the residuals only for the dependent variable; i.e., you do not assume that the regressor

***FIGURE 24*** *Several surfaces consistent with a set of multicollinear data.*

values carry uncertainty. If you need to estimate a line where both variables are treated equally, you can use orthogonal regression (see [20]), which is closely related to correlation.

## 10.5 Examples Continued

*Example 10-1:* Conduct linear regression. The slope $b$ is the rate of degradation. You can use a $t$-test to determine whether $b$ is significantly different from 0, i.e.,

***FIGURE 25*** *Regression lines where x and y have the usual (solid line) and reversed roles (dashed line).*

whether the product degrades over time. If yes, make sure there is room for this degradation between the release and shelf life limits. If these limits are given, you can predict the content at the end of shelf life from the regression line. Compare not only the predicted value to the shelf life limits but also the prediction interval.

*Example 10-2:* Construct your model based on the data from the reference samples, with concentration as regressor $x$ and degree of opacity as dependent variable $y$. You can determine the concentration for the test sample as the concentration that, when plotted into the model, results in the observed degree of opacity for this sample.

*Example 10-3:* Construct a model with two regressors: time and pressure. You can then estimate the parameters in the model, and predict the effect that changes in time and pressure will have on the yield. Beware not to extrapolate, as time and pressure very seldom yield linear responses over a large range.

# 11 NON-LINEAR REGRESSION

## 11.1 Examples

*Example 11-1:* In a stability study, the amount of a degradation product is followed. Over time, the rate of degradation becomes smaller. The concentration of the degradation product does not surpass a certain level, which is dependent on the batch. One wants to predict at an early stage whether a batch is likely to stay within the shelf life limit for the degradation product throughout its shelf life.

*Example 11-2:* In a production process, a protein is activated. The activated molecule promotes the activation of additional molecules; i.e., the rate of activation accelerates over time. One wants to determine the time point at which at least a certain percentage of the molecule is activated, as the process can be stopped at this time.

*Common background for the examples:* In both examples, one measures a dependent variable over time and models the relationship, which is non-linear. One then uses the model in much the same way as a linear regression model: For intra- or extrapolating a response for a time point where one does not have a measurement, and for determining a time point where a certain response is most likely to occur. One could also be interested in testing the fit of the model. While time is the independent variable $x$ in both examples, one could imagine any other independent variable $x$.

## 11.2 Introduction of the Tool

In general, non-linear regression is about fitting a model $y_i = f(x_i, (a, b, \ldots)) + e_i$, where $f$ is any non-linear function in $x$ with parameters $a, b, \ldots$. Below are some examples of non-linear functions that are useful as models in many situations:

*Exponential growth or decay:* The growth or decay rate, which is proportional to the current size, $f(x) = ab^x$ (see Fig. 26).

***FIGURE 26*** *Exponential growth.*

*Saturation curve*: Slowing growth, which approaches a saturation level $K$ without surpassing it, $f(x) = Kx/(b + x)$ (see Fig. 27)

*Polynomial curve:* $f(x) = ax^k + bx^{k-1} + \cdots$ (see Fig. 28)

## 11.3 Practical Details

***11.3.1 Choosing Between Non-Linear Functions*** If sufficiently many data with sufficiently high precision are available, a graph of the data may suggest a specific non-linear function that will work well for intrapolation without applying further knowledge of the mechanistic background of the data. On the other hand, if the mechanistics of the data generation process are well understood, they can suggest a specific non-linear function (see, e.g., [13]).

***11.3.2 Estimation*** Typically, there are no closed expressions for the best fitting parameters. Methods of numerical optimization, starting from a guessed value, are

***FIGURE 27*** *Saturation curve.*

***FIGURE 28*** *Polynomial curve.*

typically used (see, e.g., Reference [14]). By the best fitting parameters, one often understands those that minimize the sum of the squared residuals; i.e., one uses least square estimation. Other methods are also feasible and can be warranted in cases of non-homogenous error variances.

***11.3.3 Linearization*** In some cases, one can transform the data such that they follow a linear relationship. For example, if $y = ae^{bx}$, you can transform data by applying the natural logarithm to both sides of the equation. This results in the linear curve $\ln(y) = \ln(a) + bx$. Transformation changes the influence of the data values and the error structure. You need therefore to consider these aspects before choosing whether to linearize.

## 11.4 Traps

In general, the same traps as with regression analysis are relevant. One trap that is often ignored is extrapolation.

***11.4.1 Extrapolation*** If you use a non-linear model to predict values for the dependent variable for values for the independent variables outside the observed data range, you can be even more off the right track than when extrapolating from a regression model, because non-linear models leave you more choices. For example, if you model the population of the earth for the years 1900–2000 by an exponential growth curve, and then use the model to extrapolate to the year 2100, you end up with a population figure that, in the current understanding, is rather unrealistic.

## 11.5 Examples Continued

*Example 11-1:* The initial data can be modeled by a saturation curve with time as independent variable $x$ and the concentration of the degradation product as dependent variable $y$. If the estimate of $K$ is below the shelf life limit for the

degradation product, the entire estimated curve will be below the shelf life limit. If $K$ is larger than the limit, one can determine from the curve what the concentration of the degradation product is estimated to be at the end of shelf life. It can, however, be difficult to obtain sufficiently certain estimates of the parameters as long as data are only available from the first half of the s-curve.

*Example 11-2:* The data can be modeled in an exponential growth model with time as independent variable $x$ and concentration of the activated molecule as dependent variable $y$. From the model, the time point can be determined where the curve surpasses the desired percentage. The time point where the curve surpasses the desired percentage can be determined from the model.

In both models, neither the uncertainty of the parameter estimates nor the prediction uncertainty for a specific value is taken into account, as both can be difficult to assess. This limitation should be kept in mind when making decisions based on the model predictions.

## 12 MIXED MODELS

### 12.1 Examples

*Example 12-1:* Measurements of assay from two stability studies, each consisting of three batches, are analyzed together. The analysis is supposed to show how assay develops over time, if the development is the same for batches in the same study or, if possible, the development is the same in all batches. The response variable is assay, and variables such as batch, time, and study are explanatory variables. Measurements are made at time 0 and after 1, 3, 6, 9, 12, 18, 24, and 36 months. At each time point, a double determination of assay is made for each of the batches in the study.

*Example 12-2:* A new reference material is being calibrated against an old one. Activity is measured in an assay for both the old material and the new one. The activity is determined using a number of independent series (runs). In each series (run), several vials from each of the two reference materials are used. From each vial a dilution series of five levels is made. It is desired to model the activity as a function of the explanatory variables reference material, series, and concentration (dilution level).

*Example 12-3:* Two laboratories are using the same analysis. A study is made where samples from the same batch are analyzed at each of the two laboratories on eight days. On each day three measurements are made in each laboratory. The purpose of the analysis is to investigate if there is a difference between the two laboratories. The difference can both be in terms of level and variation.

*Common background for the examples*: In all the three examples, the variable of interest is continuous and some kind of comparison between two groups is desired. Furthermore, in Examples 12-1 and 12-2, both continuous and categorical explanatory variables are present. In Example 12-3 there are only categorical variables. It is reasonable to assume that data from all the examples can be modeled using models for normally distributed data.

## 12.2 Introduction of the Tool

There is a very general framework of models for normal data that is denoted "mixed models." Both ANOVA and regression models are part of this framework. Within this framework it is possible to model mean structures, variance components, and structures for correlations in data.

The mean function is constructed as a sum of main effects and interaction effects. The effects can both be categorical as in an ANOVA and continuous as in regression models. An interaction effect between a continuous linear and a categorical variable is a linear function for each level of the categorical variable.

In a similar fashion, variance components can be used in the model. Variance components are typically categorical factors where one is not interested in the specific levels of the factor. The levels are instead a sample of all possible levels. In Example 12-3 the day factor could very well be seen as a random factor since the specific days are not interesting – they are just a sample of all possible days, and the variation between days is just a part of the variation that the analysis is subject to.

Finally, it is also possible to model correlation structures within the framework of mixed models. Examples of correlated data could be results from the same HPLC-run as opposed to results from different HPLC-runs or repeated measurements on the same subject. It is also possible to specify different residual errors for different groups.

Within the framework of mixed models, quite complex models can be built. It is possible to model data using models that are not sub-models of each other – this is often the case when one is trying to model correlation structures. Since the models are not naturally ordered, one has to choose which model is the best. There are several approaches to determine which model fits data better [15].

## 12.3 Traps

Since there are rarely finite solutions for the estimates in the models, estimates in very complex models may depend on the choice of algorithm, number of iterations, starting values, etc. When working with a very complex model, it is wise to check that the conclusions do not depend on starting values or the choice of algorithm. Also one should consider the risk of over-fitting the model. The fewer observations one has to base an estimate on, the more sensitive the estimate becomes to outliers. The robustness of such a model should therefore be examined. Generally, model assumptions should be checked using graphical methods for the distribution and structure of the residuals.

## 12.4 Outlook: Non-Normal Data

The mixed models framework can be extended to handle other types of data than normally distributed. For a discussion of these models, see [16].

## 12.5 Examples Continued

*Example 12-1:* One way to model these data is a model where each batch has its own straight line describing the development in assay over time. It would then

be possible to test if the three batches within each study have the same slope and in case that is accepted, if the slope from the two studies are different. Another way to model the same data would be to model a common slope for each study and then model the batch deviations from the common slope as random. Again it would then be possible to test if there is a difference between the slopes from each study.

The double determinations for each batch at each time point could very well be modeled as correlated since they are performed close together in time and possibly in the same analysis run. They are handled under the same conditions, which may be quite different for another double determination performed at another time point. The difference in conditions could be different technicians, different equipment, different buffers, different room temperature, different humidity, etc. This correlation could be modeled together with the two models described above.

*Example 12-2:* One way to model the activity as a function of concentration is by a straight line for each reference material and each series. Furthermore, the residual variation could differ for each reference material. Another way could be to model the effect of series as random variations of a common straight line for each reference material. It would also be possible to model the dependency of activity on concentration as a polynomium.

*Example 12-3:* The measurements could be modeled with different means for each laboratory and day as a random effect – different for each laboratory – and finally different residual errors (within-day variance) for each of the two laboratories. From this model it is possible to test the difference in mean between the two labs and also to test if the residual errors are the same and if the effects of day are the same.

## 13 DESIGN OF EXPERIMENTS

### 13.1 Examples

*Example 13-1:* In a production process, one wants to raise the yield. There are a number of factors that may influence the yield, such as holding time, feeding speed, and various conditions of the raw materials. Which of these actually has an influence, and how large the influence is, has not been established. While a lot of personal opinions exist among the process operators, there are few data outside the current set-point.

*Example 13-2:* For an analytical method, one wants to quantify the uncertainty and learn which factors, such as analyst, equipment, reagent batches, batch of reference material, and weather conditions, have the most important influence on the measurement results.

*Example 13-3:* The yield of a chemical production process is known to be mainly influenced by temperature and pressure. One wants to determine the optimal settings of these two factors to achieve maximum yield while maintaining acceptable product quality.

*Common background for the examples:* In all examples, known variables, called factors, cause variation in some well-defined outcome. One wants to determine which factors cause the most variation in the outcome, and how much. Therefore, one sets up an experiment prospectively. One varies the factors systematically among different levels. For example, if temperature is a factor, it can be changed systematically to the levels 5°C, 25°C, and 30°C. The resulting data are then collected systematically. Thanks to the design of the experiment, they are particularly suited for the intended analysis. Furthermore, the risk that the observed variation is caused by other influences than the systematic changes in the factors is minimized. This is obtained through the prospective setup and also through specific techniques to reduce noise, such as blocking and randomization. The factors are varied simultaneously to reveal any interactions among them. While the amount of possible combinations may greatly exceed the number of experimental runs that are feasible, systematic choice of combinations makes it possible to get as much information as possible out of a limited number of experimental runs.

## 13.2 Overview of Designs

***13.2.1 Factorial Designs*** The simplest factorial design consists of two factors. Each factor is tested at two levels, i.e., two different settings for each factor. This setup results in $2 \times 2 = 4$ different combinations of factor levels or treatments. Restricting oneself to two levels is useful when examining whether a factor has an influence on the response at all. When adding a third factor, the number of treatments is doubled, as each combination of the other factor levels is examined together with both the "high" and the "low" level of the third factor. For a general number $k$ of factors, one can construct a $2^k$ factorial design.

Factorial experiments are analyzed using ANOVA if the factors are categorical, regression analysis if the factors are continuous, or mixed models if there are both categorical and continuous factors. Not only main effects between the high and low levels of a factor can be tested and estimated, but interactions between the factors can also be tested and estimated. This is one of the most important properties of designs where several factors at a time are varied.

When specifying a full model with all interaction effects, down to the $k$-way interaction of all factors, testing is not possible because the data yield no estimate of error variance with which the effects can be compared. There are several ways to address this issue:

*Replicate the full design.* This may be warranted if the variation of the outcomes for the same treatment is high compared to the differences between treatments, and the experiment is small enough to make full replication feasible.

*Replicate only one treatment.* For the sake of balance, if your factors are continuous, the replicated treatment can be a center point where all factors are set at a "middle" level.

*Do not include the highest interaction in the model, assuming it is zero.* This solution is based on the "sparsity of effects principle," which states that non-random

***FIGURE 29*** *Main effect plots: Feeding speed and glucose type have a significant effect.*

effects are sparse among all possible effects in an experiment. You can then use the variance of the highest interaction as initial estimate of error variance. When removing further interactions and main effects from the model, the error estimate improves. This is mainly useful for experiments with many factors, all of which are not expected to contribute to the variation of the outcome.

Useful tools for exploratory analysis are plots of the main effects (see Fig. 29) and the interactions that involve only few factors (see Fig. 30).

***13.2.2 Fractional Factorial Designs*** If many factors are considered in the same experiments, the number of runs necessary to try out all combinations quickly becomes very high. For example, for five factors, you need $2^5 = 32$ runs. Depending

***FIGURE 30*** *Interaction plots for two-way interactions: Feeding speed and glucose type interact.*

***FIGURE 31*** *Fractional factorial design.*

on the experiment, this may be much higher than what is technically or economically feasible. You can reduce the number of runs and still consider all factors, if you assume the higher order interactions to be zero. For example, in an experiment with three factors at two levels, you can only run one half of the $2^3 = 8$ experiments and still be able to estimate the main effects. This is so because, when ignoring any of the three factors, you still have a full factorial design in the two remaining factors (see Fig. 31). However, you cannot distinguish the main effects from the two-factor interactions. Each main effect is confounded with the two-factor interaction of the other two factors. This design is therefore only helpful if you expect the interaction effects to be negligible. It's your choice which of the two halves of the experiment you run. You may want to choose the one that includes your current standard operating conditions or avoid a combination that is particularly risky or stressful for the equipment. The two halves of the $2^3$ design are called $2^{3-1}$ designs.

With higher numbers of factors, you can choose to further reduce your designs at the cost of additional interactions, generating $2^{n-k}$ designs for any $k$ that is smaller than $n$. The figure $n - k + 1$ is called the resolution of the design. It tells you how much information you can extract from the data. The higher the resolution, the more information you get. The alias structure of a $2^{n-k}$ design tells you which main effects and interactions are confounded. It helps you to choose the right resolution and to choose between different $2^{n-k}$ designs. You should take care not to confound two effects with each other, both of which you are interested in estimating. For more details, see, e.g., [8].

***FIGURE 32*** *Central composite design.*

Factorial and fractional factorial designs rest on the assumption that the outcome depends linearly on the factors. They are therefore not suitable in cases where the outcome follows a curve, and where you want to determine the optimum in order to turn the corresponding combination of factor levels into the future standard operation condition.

***13.2.3 Central Composite Designs*** Central composite designs are constructed from factorial designs with center points by adding "star points" on or outside the faces of the factorial design (see Fig. 32). Most commonly, the star points are located at the same distance in space from the center point as the corners of the factorial design, thus distributing information evenly in the space of conditions. Each factor appears at five levels (or three, if the star points are placed on the faces of the cube represented by the factorial design), which allows estimation of curvature.

***13.2.4 Box–Behnken Designs*** Unlike factorial designs, these designs avoid treatments where all factors are set at one of their extremes. Instead, either one or all factors are set at the middle of their range (see Fig. 33). In this way, all factors are used at three levels, which allows estimation of curvature.

***13.2.5 Plackett–Burman Designs*** As fractional factorials, Plackett– Burman designs are efficient as screening designs for the detection of few large main effects among many factors. Their main advantage is their economy of runs. For example, the smallest Plackett–Burman design for 11 factors has just 12 runs. The number of runs in these designs is a multiple of four, rather than a power of two as for factorials. So it is easier to take advantage of a budget for a few more experimental runs. Main effects are, in general, heavily confounded with two-factor interactions, which makes the

***FIGURE 33*** *Box-Behnken design.*

designs less suitable for understanding interactions. The designs do not have simple graphical representations like the factorials. They are generated using algebraic tools and are available in tables and software (see, e.g., [17]).

## 13.3 Techniques for Sequential Experimenting

***13.3.1 Augmentation*** When a need for additional data arises, an experiment can be augmented by adding new runs. For example, a fractional factorial design can be augmented by another fraction of the same design, allowing some of the confounding to be resolved. A factorial design can be augmented into a central composite design, allowing estimation of curvature.

***13.3.2 Response Surface Methodology*** This methodology is used when looking for the optimum of an outcome that depends on several factors, e.g., in order to turn the optimal combination of factor levels into future standard operating conditions. It follows a sequential approach, with each experiment leading to a new experiment in an area of conditions closer to the optimum. Typically, one starts with a factorial or fractional factorial design. First, factors with significant effects are separated from those that have no significant effect. Next, a line of steepest ascent is calculated from the results of the initial experiment. Along this line, in a suitable distance from the original conditions, a second experiment is set up, typically only involving the factors that turned out significant in the first experiment. The second experiment can still be factorial and lead to a new line of steepest ascent. Contour plots (see Fig. 34) can be helpful to visualize the journey through the space of conditions. When approaching the optimum, methods can be refined by using more complicated designs, such as the central composite, by replacing the linear line of steepest ascent by a second degree polynomial and by setting a shorter distance between two consecutive experiments (see [18]).

***FIGURE 34*** *Contour plot.*

Alternative approaches exist, e.g., a technique for high-cost experiments where one set of conditions is added at a time, effectively triangulating the response surface (see, e.g., [8]).

All approaches based on finding the shortest way to the optimum assume that there is only one optimum, and if it is high, you get there by going up all the time. While this assumption often holds in real-life situations, there are more complicated situations where response surface methods can be misleading. You can, e.g., be led to a local optimum, which is far inferior to the global optimum that can only be reached by crossing a deep valley of inferior conditions. Where local optima exist in isolated places, it is easy to miss them altogether.

## 13.4 Practical Details

***13.4.1 Blocking*** Differences in outcome between experimental units, e.g., batches, analytical setups, or patients, can be large as compared to the differences between treatments. In this case, it can be difficult to detect the treatment effects. One can reduce such known, but irrelevant, sources of variation by using similar experimental units. Where this is either not feasible, or one wants to spread the experiment over a group of units that is representative for a population, one can still reduce the variation by arranging the units into similar groups and assigning treatments systematically across the groups. The technique is similar to introducing a new factor without raising the number of runs. For example, in a factorial design, one can assign one half-fraction to one block and the other half-fraction to another block.

***13.4.2 Randomization*** Not all relevant sources of variation are known. To prevent unknown sources of variation from upsetting experimental results, one uses randomization to remove any predictability from the assignment of treatments to experimental units. For example, runs are conducted in random time order, and patients are randomly assigned to the treatments in a clinical trial. Various

randomization techniques, e.g., random number tables or dice, can be used to generate a randomization. Randomization of an experiment can be complete or only partial. The latter can be relevant when blocking is used or when some factors are hard to change.

***13.4.3 Testing for Effects and Effect Estimation*** Outcomes of designed experiments are analyzed by ANOVA for categorical variables, by regression analysis for continuous variables or, if both continuous and categorical variables are involved, by estimating a mixed model.

## 13.5 Traps

***13.5.1 Is the Measurement System Adequate?*** If the uncertainty in the measurement system is large compared to the size of the effects, it can be difficult to detect and estimate the effects. One can reduce variation by repeating the experiment or by working on the measurement system to reduce its inherent variation.

***13.5.2 Are All Relevant Factors Included?*** If a relevant factor is not included in the design and varies uncontrolled and unobserved during the experiment, it can seriously upset the data. Observing conditions that are suspected to have an influence, but cannot be changed, e.g., the weather, can be relevant to understanding the outcomes. If a relevant factor is not included in the design and is constant during the experiment, the outcomes may not be predictive for a different situation where the omitted factor has changed.

***13.5.3 Are the Factors Varied Sufficiently?*** When screening for effects, it is important to vary the levels of a factor as widely as possible within the relevant space of conditions in order to raise chances that the effect is large enough to be detected.

***13.5.4 Non-Linear Responses in Factorial Designs*** When running factorial designs with their inherent assumption of linearity in a situation where an outcome does not depend linearly on the factors, one may well be lucky that the approximation is good enough for the purpose. But it is possible to run into a situation where small changes in conditions yield widely different effect estimates or no significant effect at all (see Fig. 35).

## 13.6 Examples Continued

*Example 13-1:* In this example, one would screen the factors using a factorial, fractional factorial, or Plackett–Burman design, depending on the feasible number of runs and any suspicions about interactions. One would vary the levels as widely as possible. One would consider if there are any relevant sources of variation that cannot be kept constant during the experiment. For example, if several, but not all, sets of conditions can be tried out within the same batch, batch might be a relevant blocking variable. Others might include personnel,

***FIGURE 35*** *Pairs of observations from a non-linear relationship suggesting y to decrease with x (a), increase with x (b), or be independent of x (c).*

equipment, or methods. The adequacy of the measurement system should be established prior to the experiment. Runs should be done in random order. Data are collected systematically and analyzed using ANOVA. With the learnings from the results, one might need to follow up with a second experiment.

*Example 13-2:* One lists the relevant sources of variation and sets up a factorial experiment with the sources of variation as factors. Typically, one uses samples that are as similar to each other as possible, e.g., from the same batch, or repeats the experiment for two types of samples that are known to be at the low and high ends of the analytical method's range. Days are a typical blocking factor. If weather conditions are suspected to play a role, one notes the weather conditions on the respective days. Analysis is done by ANOVA using random effects; i.e., a significant source of variation is quantified as a variance. For example, there will be a variance describing the variation between technicians in general, not a numeric difference between two specific technicians. The residual variance is the repeatability of the method, while the sum of all the variances shows the intra-laboratory reproducibility.

*Example 13-3:* A series of experiments with temperature and pressure as factors is set up according to the response surface methodology. The response variable is yield, while the measure of product quality serves as a boundary to the outcome space: Once quality is unacceptable, you backtrack.

## 14 TIME SERIES ANALYSIS

### 14.1 Examples

*Example 14-1:* A pharmaceutical company would like to forecast how much it is going to sell of a certain product in different countries. The company knows

how much it has sold previously in the countries and how many resources in terms of sales force and marketing budget it has planned to spend in the different countries.

*Example 14-2:* In a pharmaceutical production using a fermentation process, the responsible chemist would like to be able to predict how much yield he is going to get each day from the process. He knows that the yield depends on the amount of nutrition the cells have, and he believes the yield also depends on how much was harvested the previous day.

*Common background for the examples:* In both examples it is desired to forecast something (yield, amount to be sold) for specific time periods. The forecast will depend not only on some explanatory variables but also on how large the variable of interest was in the previous time period.

### 14.2 Introduction of the Tool

In time series analysis, models are built for processes where observations are made at given time intervals, e.g., daily or at each harvest from a fermentation process. Data are ordered in time sequence. The idea is to model the next observation in the process as a function of the previous observations, and sometimes also of some explanatory variables that may depend on time as well. Also the model will usually reflect the facts that observations that are close together in time are more correlated than observations further apart. Time series analysis can be used for understanding what drives a certain process and for forecasting the variable of interest. A classical example of that is in econometrics, where one forecasts the price of a share based on the price the day before. For a thorough introduction to time series analysis, see [19].

### 14.3 Examples Continued

*Example 14-1:* A time series model could be built forecasting the sale in the coming month as a function of sales in the previous months in the relevant country, the size of the sales force, and the marketing budget. It is possible to build in some kind of seasonal variation if that is meaningful (e.g., for hay fever products, or where hospital budget rounds have a major impact on sales).

*Example 14-2:* The yield from the fermentation process on a given day could be modeled as a function of the yield in the previous days and the amount of nutrition that was added the previous days. Additional explanatory variables could be included in the model.

## 15 MULTIVARIATE ANALYSIS

### 15.1 Examples

*Example 15-1:* A fermentation process generates a wealth of data. At regular intervals throughout the process, measurements are recorded for process parameters such as feeding speed for various ingredients and paddle speed,

as well as for process outcomes such as temperature, pH, and cell counts. Many of these measurements are correlated. A collective analysis of data from a range of batches is intended to yield a better understanding of how the many different parameters and outcomes are related to each other.

*Example 15-2:* Near Infrared Spectroscopy (NIR) method is used to determine water content in freeze-dried samples. The primary result of measurement is a spectrum, consisting of many different data points for each measurement. When calibrating the method, samples are analyzed first using NIR and afterward by Karl Fischer titration, which results in a reference measurement. The aim of the calibration is to link the many data of the spectrum for each sample to the single Karl Fischer result for this sample. The link allows then to read a water content figure from the spectrum, which means to predict the Karl Fischer result.

*Example 15-3:* From a fermentation process, a number of harvests are drawn throughout the process. The content of one degradation product, as determined by chemical analysis, follows a characteristic curve throughout the full length of the process. One wants to determine at various time points during the process whether the profile follows the usual curve or develops into a different profile.

*Common background for the examples:* In all examples, data consist of a large number of variables that are correlated. Multivariate modeling allows for using the full range of data while preventing correlation from introducing ambiguity to the model.

## 15.2 Introduction of the Tool

***15.2.1 Principal Component Analysis (PCA)*** The correlation structure in a multi-dimensional dataset is analyzed and used for compressing the dataset into a set of lower dimension. Instead of a large number of original variables that are correlated, the compressed dataset consists of a smaller number of principal components that capture the majority of the variation in the original dataset and are not correlated, see Fig. 36. The number of components indicates how much independent information there is in the

***FIGURE 36*** *Small multivariate dataset with principal components.*

dataset. The principal components are linear combinations of the original variables. The contribution of each variable to a principal component is called its loading. The loadings can give an understanding of the correlation structure and possible interpretations of the principal components. For a thorough introduction, see, e.g., [21].

***15.2.2 Factor Analysis*** In this analysis, the observed variables are assumed to be linear combinations of underlying factors. The method was developed in psychometrics, where, e.g., the observed variables were test scores, and an underlying factor could be intelligence. The factors are estimated from the data. If the error terms of the linear combinations are assumed to be equal, this analysis is closely related to PCA.

## 15.3 Examples Continued

*Example 15-1:* PCA can be used to reduce the wealth of variables to a smaller number of independent principal components, by which the batches can be characterized. By examining the loadings, one can get an understanding of how the variables group and contribute to the principal components. Graphical methods are recommended to support this process towards understanding the correlation structure.

*Example 15-2:* PCA can be used to go from the many data per spectrum, one for each recorded wavelength, to one principal component. Then the relation between the spectrum's principal component score and the content determined by Karl Fischer can be modeled by a relevant method, e.g., linear regression. With the model in place, the component score can be determined for each new spectrum, and the content, as it would have been determined by Karl Fischer, can be estimated.

*Example 15-3:* PCA or factor analysis allows to reduce the profiles into one or a few components. For these, ordinary or multivariate SPC can be established. One can do this not only for the full profiles but also for profiles up to a certain time point. During the production of a batch, one can determine the principal component score of the batch and enter it into the process control chart for the relevant time point. If a batch wanders beyond the control limits, this is a sign that the profile is clearly distinct from the usual profiles. A simpler and possibly comparably effective approach to detecting aberrant profiles may be to plot the profiles directly against a representative collection of profiles from earlier batches.

# *Systems-Based Approach to Laboratory Compliance with the Current Good Manufacturing Practice (CGMP) Regulations*

**David M. Bliesner**
*Delphi Analytical Services, Inc., Indian Rocks Beach, Florida*

## 1 INTRODUCTION

In January 2001 the FDA issued the document Compliance Program Guidance Manual (CPGM) 7356.002 titled "Drug Manufacturing Inspections (Pilot Program)." This manual provided guidance to FDA personnel for conducting inspections of pharmaceutical manufacturing sites in an efficient and structured fashion (1). The objective of this manual was to implement a quality systems-based approach to enforcing 21 CFR parts 210 and 211, the Current Good Manufacturing Practice (CGMP) regulations (2). In February 2002 the FDA formally adopted this guidance

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing,*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

manual and in August of that same year announced the Pharmaceutical CGMPs for the 21st Century Initiative. This initiative explained the agency's intent to integrate quality systems and risk management approaches into all its existing programs, the goal of which was to encourage industry to adopt more modern and innovative technologies. Subsequently, in September 2006 the FDA issued a guidance to industry entitled "Quality Systems Approach to Pharmaceutical CGMP Regulations" (3). This guidance document built upon the principles delineated in CPGM 7356.002 and bridged the gap between CGMPs and the current industry understanding of quality systems.

The guidance describes in a straightforward manner a comprehensive quality systems model for manufacturing drugs that, if properly implemented, not only ensures compliance with the CGMPs but also ensures manufacturers provide high-quality drug product to patients and prescribers. The bottom line is that a quality systems-based approach to drug product manufacturing is just good business. As in CPGM 7356.002, the guidance document describes an inspectional model that divides the operations of pharmaceutical manufacturing into six systems. These include (1) the quality system, (2) the packaging and labeling system, (3) the production system, (4) the facilities and equipment system, (5) the materials system, and (6) the laboratory control system. The diagram below shows the relationship among these six systems. Note that the quality system provides the basis for the other five manufacturing systems that are linked and function within it.

Of these five "inner" systems, the laboratory control system remains perhaps one of the most difficult to understand and master and leads to numerous quality failures.

A cursory review of Warning Letters listed on the FDA Web site http://www.fda.gov/foi/warning.htm shows that the laboratory is *rarely not* part of the regulatory action.

The root causes for lack of compliance with the CGMPs within the laboratory control system are perhaps most directly related to the multifunctional aspects of laboratory operations in general. In addition, many of the responsibilities within the laboratory are truly unique to that environment and vary somewhat from laboratory to laboratory depending upon the product line and size of the company. For example, a small generic solid dosage form manufacturing may have only a few established products and a few test methods. Compare this to a large innovator company that is constantly developing, validating, and testing new and different products. This means that each of these laboratories may require specific instrumentation, methods, and uniquely qualified personnel to execute the job functions. Because of this the laboratory control system is actually a collection of "systems within the system," each requiring special consideration and care.

However, for the purposes of most discussions, the laboratory control system can be divided into at least seven different sub-elements that are required to ensure overall compliance with the CGMPs. These include (1) Laboratory Managerial and Administrative Systems, (2) Laboratory Documentation Practices and Standard Operating Procedures, (3) Laboratory Equipment Qualification and Calibration, (4) Laboratory Facilities, (5) Methods Validation, (6) Laboratory Computer Systems, and (7) Laboratory Investigations.

The intent of this chapter is to demystify the laboratory control system and to help people understand each of the sub-elements that are simply "systems within the system" and are required for smooth and compliant laboratory operations of a typical analytical laboratory. To accomplish this, each of the seven laboratory control system sub-elements is analyzed in more detail. Specifically, this analysis takes the form of a series of questions an FDA inspector may ask during a pre-approval inspection (PAI) or a manufacturing site biennial inspection.

## 2 LABORATORY MANAGERIAL AND ADMINISTRATIVE SYSTEMS

Laboratory managerial and administrative systems are those sub-elements that provide the infrastructure for efficient and compliant operations of an analytical laboratory. It is sometimes difficult to directly relate items within this sub-element to the CGMPs. However, deficiencies within this sub-element that cannot be directly attributed to the CGMPs can lead to compliance failures. For example, 21 CFR parts 210 and 211 do not specifically require that someone be assigned the duties of training manager. However, failing to have an individual responsible for training and consequently not have an effective training program can degrade the overall quality of data that are generated by laboratory personnel.

The Laboratory Managerial and Administrative Systems sub-element includes at least eight individual topics. A laboratory that is in compliance with CGMPs should at least address each of these topics (as applicable). These topics include (1) Organizational Structure and Roles and Responsibilities, (2) Training, (3) Tracking

and Trending-Statistical Quality Control, (4) Complaints, (5) Laboratory Purchasing and Requisition, (6) Laboratory Administration, (7) Laboratory Chemicals, Solutions, Reagents, and Supplies, and (8) Laboratory Reference Standards and Solutions. These eight topics are listed below in the form of possible questions an FDA inspector may ask when conducting an audit of the laboratory. The list of items under each topic is fairly comprehensive but may not be totally inclusive of all those components that may constitute the sub-element.

---

**LABORATORY MANAGERIAL AND ADMINISTRATIVE SYSTEMS SUB-ELEMENT**

*Organizational Structure and Roles and Responsibilities*

Are current organization charts available and accurate?
Is there a policy/procedure that defines the responsibility and authority of the Quality Control Unit?
Have the responsibilities of each functional group and supervisor been clearly defined, including testing and operational requirements, SOPs, and all other critical functions?
Is an organizational structure in place that is properly staffed to assure that all required testing/monitoring and support activities are performed?
Is the span of control and authority assigned to the Quality Control adequate to allow proper execution of these activities?
What is the ratio of supervision to analyst (8:1 recommended)?
Are the roles and responsibilities for each position clearly defined?
Are job descriptions available?
Are signature authority, responsibility, and accountabilities appropriate and clearly defined?
Do systems exist to enhance communications, understanding, and working relationships between laboratory and Quality Assurance personnel?
Does a personnel performance evaluation system exist that tracks laboratory personnel strengths and weaknesses and establishes corrective action procedures to mitigate any weaknesses?
Does a master testing schedule or similar document(s) exist to ensure smooth workflow and minimize laboratory personnel over commitment?
Do current CVs and resumes exist for all personnel including consultants?

*Training*

Have the educational, training, and work experience requirements for each laboratory position been clearly defined and do they reflect current standards in the industry?
Are training requirements clearly documented in an SOP or similar guidance document (including managers, supervisors, analysts, and temporary staff)?
Has a training curriculum been developed for each position that clearly identifies training requirements for all required SOPs and policies, safety procedures, CGMPs, as well as all other internal and external courses or programs? (Database or hard copy?)
Is job-specific training identified and executed (e.g., laboratory analyst qualification system)?
Does each employee have a training file or similar record?
Are the training histories for each individual employee kept current? (Database or hard copy?)
Have all laboratory personnel been properly trained?
Is this training documented and are the documents available for review?
Is SOP training conducted in a fashion other than “read and understand”?
Are metrics used to determine effectiveness of SOP training?
Is there an analyst qualification program in place?
Has an individual been designated as the training coordinator or manager?
Is there evidence of management support for training and training programs?
Does a formal training budget exist?
Do vendor training records exist?
Is there evidence that newly hired employees are evaluated for skill level and competency?

**TABLE** (*Continued*)

Is there a formal training schedule in place and is it being executed?
Is there evidence of employee re-training and re-qualification?
Is there a positive attitude with respect to training on the part of management and laboratory personnel?
*Tracking and Trending-Statistical Quality Control*
Is tracking and trending (e.g., control charting) of data performed with the following points to be considered:

- For finished product testing?
- For raw material testing?
- Procedures delineated in an SOP?
- Appropriate periodic evaluation of control chart data included annual product reviews?
- Appropriateness of response to evaluations (e.g., excursions or trends are formally addressed as per SOP)?
- For finished product stability data (release and retain samples)?

*Complaints*
Is there a formal product complaint handling system in place, including some system of complaint monitoring, and statistical review with the following points to be considered:

- Procedures delineated in an SOP?
- Site procedures consistent with standard industry practice?
- Quality Control laboratories are involved and provide testing as appropriate?

*Laboratory Purchasing and Requisition*
Are levels of approval defined and appropriate for purchasing and requisitions for the laboratory?
Are items purchased from qualified vendors (e.g., raw materials, reagents, standards, and instruments)?
Does the laboratory have a defined yearly budget? Is the budget derived from existing data and projected workloads?
Does the laboratory have a defined capital budgeting process? Is the budget derived from existing data and projected needs?
Does the laboratory have a defined process for requesting and receiving approval to hire new personnel?
Does the laboratory have specific personnel assigned to purchasing and budgeting activities?
Do these personnel have the proper skills and training to perform planning, budgeting, and purchasing activities?
*Laboratory Administration*
Does the laboratory have a general administrator, office manager, or similar administrative support person?
Is someone assigned the responsibility for:

- Managing work orders for office and laboratory repairs?
- Budget preparation, oversight, and review?
- Overseeing stockroom operations?
- Supervising requisition of administrative and operational supplies?
- Managing external contractors and contracts?
- Managing/enhancing communication between the laboratory and internal/external customers?
- Supervising laboratory safety training and compliance?
- Monitoring overtime billing?
- Capital equipment purchases?
- Supervising administrative service personnel such as maintenance and calibration, laboratory computers, documentation section, and training section?

Are there laboratory corrective and preventive action committees, or similar groups in place?
Are the laboratory corrective and preventive action committees' meeting minutes published and proposed actions communicated to all appropriate personnel?
Are data reported in all types of reports easily traceable to raw data?
*Laboratory Chemicals, Solutions, Reagents, and Supplies*

**TABLE** (*Continued*)

| |
|---|
| Is there a written procedure for receipt and storage of chemicals and reagents? |
| Are chemicals and reagents properly labeled with date of receipt, date opened, and expiration and re-test dates? |
| Are laboratory-prepared reagents and solutions properly identified (e.g., chemical name or symbol, concentration, date of preparation, initials of the analyst who prepared it, and expiration date)? |
| Are records available to document preparation and standardization of volumetric solutions? |
| Is the frequency of standardization of various reagents described? Is it consistent with the current USP? |
| Are standardized reagents properly stored to assure integrity? |
| Are there procedures that describe the preparation of laboratory reagents and cultures? |
| Are there procedures that describe the maintenance of laboratory reagents and cultures? |
| *Laboratory Reference Standards and Solutions* |
| Is there a written procedure for ordering and receipt of compendial reference standards and non-compendial reference standards? |
| Are the primary standards of the current lot listed in the USP, EP, or JP? |
| Is the receipt of the standards logged? |
| Are all standards labeled with name, source, lot number, and expiration date? |
| Do written procedures include provisions for prevention of contamination of primary standards? |
| Are standards stored in a secured area under environmentally controlled and monitored conditions? |
| Are procedures for assuring standard integrity available? |
| Are working or "house" standards checked against primary standards at appropriate intervals? |
| Are stock solutions appropriately identified, and is their expiration based on their true stability? |
| Do procedures exist for the certification and use of non-commercially available reference standards? |
| Do certificates of analysis exist for all reference standards and are these certificates stored as controlled documents? |
| Have provisions been made for handling controlled substance reference standards? |
| Does the reference standard SOP address (map) proper handling of controlled substance reference standards? |

## 3 LABORATORY DOCUMENTATION PRACTICES AND STANDARD OPERATING PROCEDURES

Laboratory Documentation Practices and Standard Operating Procedures form a critical component of the overall laboratory control system. Much of the essence of CGMPs involves the generation, review, approval, revision, and control of procedures and data. In compliance parlance, "If it isn't written down, it didn't happen."

Laboratory Documentation Practices and Standard Operating Procedures subelement includes at least nine individual topics. A laboratory that is in compliance with CGMPs should address each of these topics (as applicable). These topics include (1) SOPs-General, (2) SOP-Specific Procedures, (3) Laboratory Test Procedures, (4) Laboratory Data and Results, (5) Security of Data, (6) Distribution of Results, (7) Chromatography, (8) In-Process Testing, and (9) Assignment of Re-Test/Expiry Dates.

These nine topics are listed below in the form of possible questions an FDA inspector may ask when conducting an audit of the laboratory. The list of items under

each topic is fairly comprehensive but may not be totally inclusive of all those components which may constitute the sub-element.

---

**LABORATORY DOCUMENTATION PRACTICES AND STANDARD OPERATING PROCEDURES SUB-ELEMENT**

*SOPs-General*

Is there a comprehensive and current laboratory document control system in place?
Is there a list of all approved SOPs?
Are the SOPs current, clearly written, and accessible to all appropriate personnel?
Is there a system for periodic review of all SOPs to ensure that they are consistent with current company and industry practices?
Is there an SOP governing the SOP or document control system (e.g., an SOP on SOPs)?
Is there a system for controlling the issuance and revision of all SOPs?
Do policies and manuals exist that supplement the SOPs (e.g., Level I and Level II guidance documents)?
Are the guidance documents readily accessible to all laboratory personnel?
Are all SOPs reviewed and updated at least every year?

*SOP-Specific Procedures*

Are there specific standard operating procedures covering:

- Change control?
- Record review and approval requirements?
- Description of the requirements for performing data review?
- Laboratory records (e.g. data recorded in bound notebooks or controlled worksheets)
- Dissolution testing?
- Sample receipt, documentation, handling, storage, and control?
- Laboratory investigations, deviations, and handling of out-of-specification (OOS) results?
- Policy for identification and reporting of new impurities and/or higher levels of previously known impurities?
- Validation and transfer of analytical methods?
- Laboratory computer validation?
- Preparation, labeling, identification, expiration-dating, and storage of chemicals, reagents, and solutions?
- Equipment/instrument use, preventive maintenance (PM), calibration, and qualification?
- Appropriate labeling of out-of-use lab equipment?
- Glassware washing (mechanical and manual)?
- Practices regarding housekeeping, safety glasses, eating in labs, smoking, etc.?
- Hazardous waste disposal?
- Handling and disposing laboratory samples?

Is there an SOP for defining appropriate sampling plans for all Quality Control laboratory testing?
Are samples randomly chosen and are they representative of all portions of the lot(s)?
Is there an SOP for the receipt, documentation, handling, storage, and distribution of laboratory samples?
Is a sample logbook maintained?
Are samples tracked? Is sample disposition included in tracking?
Are storage areas maintained for sample disposition (e.g., retention and destruction)?
Is there a master signature list, including person names, initials, and responsibilities?
Are samples labeled appropriately to include sample description, source, quantity, date sampled, date sample received for testing?
Are sample storage areas properly identified and maintained?
Is there a backlog with respect to sample analysis, and if so, is the backlog great enough to have an impact on testing results and product release?

*Laboratory Test Procedures*

Is there an index listing the testing documents and specifications?
Is this list updated and properly controlled?

**TABLE** (*Continued*)

Do the test procedures include sufficient instructions on how to conduct the testing and operate the specific lab instruments?
Is there a system for controlling the issuance and revision of all testing-related records?
Are laboratory test procedures and specifications approved by the Quality Assurance Unit?
Is there a written change control procedure that describes how analytical method changes are made?
Do specifications for compendial products meet compendial requirements?
Is there a procedure for determining "in-house" or tighter release specifications?
Are raw materials released by using validated analytical methods?
*Laboratory Data and Results*
Are data documented in bound pre-numbered logbooks, notebooks, or other data storage and acquisition systems?
Is the use of scrap paper, "post-its," or similar uncontrollable paper specifically prohibited in the laboratory?
Are corrections to data entry errors covered in an SOP?
Are all handwritten documents/data recorded in permanent ink?
If bound notebooks are used, is there a system for control, issuance, use, and return?
Is each notebook page dated and signed by the analyst and second reviewing authorized individual and performed in a timely manner?
Are all entries checked and approved for completeness of sample identity, proper use of reagents, standards, and execution of experimental procedures?
Are all outputs such as chromatograms and spectra appropriately identified, stored, referenced to notebooks, and readily retrievable?
Are all data, calculations, and results verified by second qualified individual for accuracy, completeness, and compliance with specifications?
Are the qualifications of persons conducting data review documented and acceptable?
Is data review documented by full signature and date?
Are data review and approval activities captured in LIMS?
Are data reviewed by the laboratory and approved by the Quality Assurance Unit before distribution? Is this process defined by an SOP?
Is there a system in place to assure that the method being used in the laboratory is the current approved version method for testing?
Is the method used for analysis recorded onto the laboratory testing results sheet or recorded into a LIMS?
Is there a written SOP for handling of re-integration of HPLC/GC data?
If a computer software package is used to calculate results, is there an example calculation included with the reported results verifying proper algorithm execution?
Are all correction factors used in calculations expressed with the proper units?
Are raw data defined in an SOP?
*Security of Data*
Is access to stored data limited?
Are data protected from fire, water, and other environmental hazards?
Are data readily retrievable?
Is the length of time that documents need to be retained defined in writing and does this time frame meet current industry practice?
Are backup copies of data stored at an off-site location?
Is there a disaster recovery plan, and has it been rehearsed?
*Distribution of Results*
Are results entered into a LIMS or other electronic management system?
Is LIMS used to compare testing results to the specifications for determining "pass/fail" decisions?
Is LIMS used to provide data for use in annual product reviews?
If data are transcribed from notebooks and reports, is transcription accuracy being verified?
*Chromatography*
Is system suitability performed routinely (e.g., HPLC methods, GC methods)?

**TABLE** (*Continued*)

| |
|---|
| Are the system suitability parameters determined from validation data? |
| Must system suitability parameters be calculated and met prior to executing a quality control sample analysis? |
| Is there an SOP that delineates a standard sample queue (i.e., interspersing of standards and samples during the course of the chromatographic run)? |
| *In-Process Testing* |
| Are validated methods used for in-process testing? |
| Do formal sampling plans exist for all in-process testing? |
| Are there established acceptance criteria/ranges/specifications for the in-process tests? |
| Is sample integrity preserved during handling and storage of in-process samples? |
| Are all the necessary industry standard in-process tests conducted (e.g., blend uniformity, weight variation, hardness, thickness)? |
| *Assignment of Re-Test/Expiry Dates* |
| Are expiration/re-test dates based on available in-house storage (stability) data or otherwise justified? |
| Does an SOP exist that differentiates between re-test and expiry dating? |
| Is there a limit for extending the re-test life of the substance evaluated? |
| Are there procedures for handling/storage of reference standards and reference cultures? |

## 4 LABORATORY EQUIPMENT QUALIFICATION AND CALIBRATION

Since the vast majority of data in a modern analytical laboratory are acquired via instrumentation, it is essential that these instruments have been properly installed and qualified, and are kept in proper working order. The Laboratory Equipment Qualification and Calibration sub-element addresses these issues.

Laboratory Equipment Qualification and Calibration includes at least three individual topics. A laboratory that is in compliance with CGMPs should address each of these topics (as applicable). These topics include (1) Laboratory Equipment Procedures-General, (2) Laboratory Equipment Procedures-Specific, and (3) Laboratory Equipment Procedures-Computer Controlled.

These three topics are listed below in the form of possible questions an FDA inspector may ask when conducting an audit of the laboratory. The list of items under each topic is fairly comprehensive but may not be totally inclusive of all those components that may constitute the sub-element.

| **LABORATORY EQUIPMENT QUALIFICATION AND CALIBRATION SUB-ELEMENT** |
|---|
| *Laboratory Equipment Procedures-General* |
| Are the laboratories equipped with all of the necessary instruments for the analytical testing to be performed? |
| Is there a written qualification, calibration, and PM program in place that is described in an SOP? |
| Is there a master equipment list available and is it properly maintained? |
| Is there a master equipment maintenance and calibration schedule? |
| Are specific personnel assigned to maintain the master equipment list and equipment maintenance and calibration schedule? |
| Are calibration/service vendors qualified and are their training records available? |

**TABLE** (*Continued*)

| |
|---|
| Is there a validation master plan, which indicates timing and responsibility for equipment qualification and re-qualification? |
| Are there "triggers" (e.g., specific criteria and/or circumstances) for re-qualification, and are they integrated into the master plan? |
| Does each piece of equipment have a logbook or file that documents instrument maintenance, calibration, and repair histories? |
| Does each piece of equipment have a usage log? |
| Do labels on the instruments identify the person who performed the calibration, date of calibration, and due date of next calibration? |
| Are IQ/OQ/PQ requirements, which clearly define performance testing acceptance criteria for each piece of equipment, clearly defined in an approved protocol? |
| Has IQ/OQ/PQ been performed and properly documented for all equipment? |
| Is IQ/OQ/PQ performed during initial system installation? |
| Are calibration and PM, including tolerances, based on the manufacturer's recommendations? |
| Are cleaning procedures included in the SOPs for instrument qualification or calibration? |
| Is there an SOP that requires that instruments failing calibration are removed from service? |
| Does the SOP provide directions for investigations when instrumentation is found to be out of calibration, yet still is being used to generate CGMP data? |
| Are the qualification specifications for equipment based on sound scientific principals? |
| Are calibration/metrology records secure (locked up)? |
| *Laboratory Equipment Procedures-Specific* |
| Are balances checked for corner loading? |
| Are pH meters standardized and calibrated? |
| Are balances calibrated at both upper and lower weighing capability using NIST traceable standards? |
| Are calibration correction factors attached to thermometers (if appropriate)? |
| Are pH meters calibrated at two points, not differing by more than 4 pH units? |
| Are UV spectrophotometers calibrated for wavelength and photometric accuracy? |
| Is there a written procedure for setup, calibration, and operation of dissolution baths? |
| Are there written procedures for calibration and maintenance of HPLCs, including pumps, autosampler reproducibility, and wavelength accuracy? |
| Do HPLC PMs include seal and valve changes? |
| *Laboratory Equipment Procedures-Computer Controlled* |
| Is there a written policy or procedures for validation of computer-interfaced instrumentation? |
| Have the computer systems/software, which control instruments, been validated? |
| Is there a system in place to install new software versions and to decide what scope of re-validation must be done during software upgrades? |
| Is computer software validation a part of the OQ process? |
| Is the computer software validation documented? |
| Are there systems in place to prevent installation of unauthorized software? |
| Are integrators validated using a validated signal generator? |

## 5 LABORATORY FACILITIES

As with a manufacturing area, it is essential that the laboratory be properly designed and equipped. This ensures that the data generated accurately reflect the true composition of the sample from which they came. In addition, it ensures a safe working environment for laboratory personnel.

The Laboratory Facilities sub-element includes three individual topics. A laboratory that is in compliance with CGMPs should at least address each of these topics (as applicable). These topics include (1) Laboratory Facilities-General, (2) Safety and Environmental Concerns, and (3) Laboratory Glassware.

These three topics are listed below in the form of possible questions an FDA inspector may ask when conducting an audit of the laboratory. The list of items under each topic is fairly comprehensive but may not be totally inclusive of all those components that may constitute the sub-element.

---

**LABORATORY FACILITIES SUB-ELEMENT**

*Laboratory Facilities-General*

Are the physical construction of the laboratory areas adequate for testing and all routine activities with respect to:

- Size?
- Layout and design for optimum workflow and efficiency?
- Sample receipt?
- Appropriate tables for balances/instruments, etc.?
- Location of SOPs, location of methods, specification sheets, and safety data sheets?
- Location of reagents, standards, solutions, and solvents?
- Data entry, recording, writing areas?
- Sample storage and retention?
- Refrigeration?

Are proper systems in place to minimize cross-contamination during sample preparation and laboratory testing?

Are all controlled temperature/humidity storage areas, incubators, etc. monitored to assure that proper conditions are maintained?

Have temperature monitoring systems and equipment been properly validated?

Have humidity monitoring systems and equipment been properly validated?

Are controlled substances properly segregated and controlled according to DEA requirements?

Is the environment/temperature control correct for the areas for different types of equipment?

Are radioisotopes (if used) in proper storage areas?

*Are uninterruptible power supply (UPS) units used to minimize the impact of power surges and outages?*

If an UPS exists, has it been qualified and has an SOP describing its use been written?

Are piping systems specified at the correct pressure, and have they been cleaned, flushed, leak tested passivated (sanitary use), and certified?

Have appropriate hood air filters been installed and smoke tests performed?

Have facility monitoring systems been validated?

Have purified water systems been validated?

Is there an SOP for lab or engineering maintenance of the air system?

*Are there appropriate controls/specifications for handling particulate matter and microbes available?*

Is there control of HVAC in instrument rooms, balance area, etc.?

Does the hood exhaust into an appropriate location (e.g., a sufficient distance from the air intake system as to not interfere with lab operations)?

Is the HVAC for stability/retention samples adequately monitored?

Has the laboratory water system been properly qualified?

Is there routine monitoring to assure adequate quality of the water?

Are the types of water required for the lab identified, and are specifications properly set?

Is lab water part of the site water monitoring program, and is testing frequency established and appropriate?

Are there action plans for following water related out of specification results or deviations?

Is there a schedule for servicing the laboratory water system?

**TABLE** (*Continued*)

| |
|---|
| *Safety and Environmental Concerns* |
| Is there a safety and environmental SOP? |
| Is there testing of hoods? |
| Are hazardous materials identified and segregated? |
| Are safety data sheets available, and are they kept current? |
| Is there a program that describes handling and disposal of biohazardous waste? |
| Are toxic/dangerous chemicals handled and disposed of according to local, state, and federal regulations? |
| Are employees trained to handle toxic/dangerous materials? |
| *Laboratory Glassware* |
| Has glassware washing/cleaning been validated to include demonstrating the removal of chemical residue? |
| Is there a PM program for mechanical glassware washers? |
| Is there a program in place to check for defective and worn glassware? |

## 6 METHODS VALIDATION AND TECHNOLOGY TRANSFER

Methods validation is the process of demonstrating that analytical procedures are suitable for their intended use. The methods validation process for analytical procedures begins with the planned and systematic collection validation data to support analytical procedures. In addition, the methods validation process is considered to be complete once the methods have been successfully transferred from the originating to the receiving or end user laboratory.

The Methods Validation and Technology Transfer sub-element includes at least three individual topics. A laboratory that is in compliance with CGMPs should at least address each of these topics. These topics include (1) Validation of Analytical Methods-General, (2) Cleaning Methods Validation, and (3) Procedures for Methods Transfer.

These three topics are listed below in the form of possible questions an FDA inspector may ask when conducting an audit of the laboratory. The list of items under each topic is fairly comprehensive but may not be totally inclusive of all those components that may constitute the sub-element.

**METHODS VALIDATION AND TECHNOLOGY TRANSFER SUB-ELEMENT**

*Validation of Analytical Methods-General*

Is there a general SOP for methods validation?

Are the requirements in the SOP consistent with FDA/ICH/USP guidelines?

Are methods validation protocols used for each validation?

Are all of the appropriate elements of validation included in the methods validation protocol such as:

- Accuracy?
- Precision (repeatability and intermediate precision)?
- Selectivity/specificity?
- Robustness?
- Linearity?
- Range?
- Limit of detection?

**TABLE** (*Continued*)

- Limit of quantitation?
- System suitability?
- Sample solution stability?
- Completeness of extraction (from dosage forms)?
- Filter retention studies?
- Forced degradation studies?

Is there an SOP or section within an SOP, which discusses the requirements for the verification of compendial methods?
Have compendial methods been shown to work under the actual conditions of use?
Have impurity methods been properly validated? Are they stability indicating and selective or specific?
Are methods validation reports published following validation of an analytical method?
Can results presented in the methods validation reports be tracked back to raw data?
*Cleaning Methods Validation*
Is there an ongoing cleaning validation program in place?
Is cleaning validation conducted according to a master plan and schedule?
Are there validated sampling procedures developed to support cleaning validation studies?
Are there written acceptance criteria?
Were recovery studies conducted?
Are there validated analytical methods developed to support cleaning validation studies?
Does the cleaning validation testing include analysis of area swap samples?
*Procedures for Methods Transfer*
Are there site policies and procedures governing transfer of methods, and do these documents include defining acceptance criteria?
Are the responsibilities for who is in charge clearly defined (e.g., receiving laboratory or originating laboratory)?
Is there a requirement to form an analytical technology transfer team or similar organization to transfer methods?
Is a formal receiving laboratory readiness assessment performed to include evaluation of equipment, facilities, and personnel?
Is the receiving laboratory given the opportunity to review the analytical methodology prior to the transfer process?
Is an analytical technology transfer qualification strategy document generated and used to guide the transfer of methods?
Are personnel in the receiving laboratory given the opportunity to use the method under the supervision of the originating personnel subject matter experts prior to formal transfer?
Is an analytical technology transfer protocol, with pre-determined acceptance criteria, used to formally transfer the methodology?
Is a reviewed and approved technology transfer report generated upon successful execution of the transfer protocol?
Can results presented in the cleaning methods validation reports be tracked back to raw data?

## 7 LABORATORY COMPUTER SYSTEMS

In a modern analytical laboratory, nearly every instrument either is controlled by or has data residing and processed by a computer. Subsequently, it is critical that reliability of these systems and their associated software be evaluated.

The Laboratory Computer Systems sub-element includes at least seven individual topics. A laboratory that is in compliance with CGMPs should address each of these

topics (as applicable). These topics include (1) Laboratory Computer Systems-General, (2) Centralized and Network-Attached Data Systems, (3) Stand-Alone Data Systems, (4) SOPs and Records, (5) Laboratory Information Management System (LIMS), (6) Spreadsheets, and (7) Other Systems.

These seven topics are listed below in the form of possible questions an FDA inspector may ask when conducting an audit of the laboratory. The list of items under each topic is fairly comprehensive but may not be totally inclusive of all those components that may constitute the sub-element.

---

**LABORATORY COMPUTER SYSTEMS SUB-ELEMENT**

*Laboratory Computer Systems-General*

Is there an inventory of laboratory data systems (both centralized and benchtop systems) including any associated servers?
Is a disaster recovery plan in place addressing laboratory data systems?
Has it been tested?
Is documentation for the plan and any tests available for review?
Have all GMP laboratory data systems and associated file servers, etc. been validated in accordance with applicable standards and procedures?
Have all GMP laboratory data systems and associated file servers, etc. been reviewed for compliance with 21 CFR Part 11?
Is there a remediation/replacement plan for those that were found to be deficient?
Are GMP workstations clearly labeled as such?
Is access to laboratory workstations provided through operating systems that have individual user accounts?
Are passwords properly controlled and protected by the end users?
Are passwords properly managed with assignment of permissions and privileges?
Are workstations configured with password-controlled screensavers or other automatic locking mechanism?
Are data structures for laboratory systems documented?
Does this include defining folders/directories on local hard drives and file servers where data are stored?
Do system SOPs specify these folders/directories for data storage as appropriate?
Are procedures in place to govern data naming conventions for projects, analyses, products, etc.?
Is data “archiving” performed on one or more laboratory data systems?
Is the distinction between archiving and backing up data understood by laboratory staff?
Is archived data subject to formalized retention standards?
Has the de-archival process ever been tested?

*Centralized and Network-Attached Data Systems*

Are backups of data files made regularly?
Is it governed by SOP?
Is there an individual who is assigned this responsibility?
Is the backup media securely stored, with inventory data that are current and accurate?
Are there documented service-level agreements with the central support organization defining mutual expectations and responsibilities?
If backups are performed by an automatic procedure provided by a central support organization, is clear documentation in place to define expected data structures and problem-alerting/resolution procedures?
Are data restores governed by an SOP?
Are the restores documented as required by SOP?

**TABLE** (*Continued*)

Does the central support organization have server/application SOPs, which address data management, incident management, performance monitoring, etc., specific to the laboratory?

*Stand-Alone Data Systems*

Are backups performed either automatically (scheduled through a system procedure) or manually as defined by SOPs?

Is there a procedure in place to determine whether backup media have been modified?

Are backup media identified and securely stored?

Are the restores documented as required by SOP?

*SOPs and Records*

Do SOPs exist for validation of laboratory data systems?

Have appropriate laboratory staff been trained on the laboratory data system SOPs?

Are training records for personnel trained on the SOPs available for review?

Do SOPs exist for operation of CGMP laboratory data systems?

Have appropriate laboratory staff been trained on the SOPs for CGMP laboratory data system operation?

Are training records for personnel trained on the SOPs available for review?

*Laboratory Information Management System (LIMS)*

If a LIMS is used for data management (either custom or commercial system), has it validated?

Has the validation been properly documented, and are data available for review?

Is the system operated and maintained by laboratory staff or a systems support organization?

Is the system maintained under change control that is delineated in an SOP?

Have lab personnel been trained on LIMS data entry, and are training records available for review?

Are there automated data entry and extraction points in the LIMS? Have the links been validated for:

- Bar code readers?
- GC data stations?
- HPLC data stations?
- Balances?
- Spreadsheets?
- Other components?

Is there a definition of what are considered raw data?

Can data entries be made by only authorized, password-protected individuals?

Are electronic signatures used in the LIMS, and are they in compliance with 21 CFR Part 11?

*Spreadsheets*

How are spreadsheets used in the laboratory, and if so, do they reside on the following:

- Networks?
- Workstation hard drives?

Are procedures in place governing the development/modification of spreadsheets for GMP use?

Are the spreadsheets in use unalterable and qualified/validated?

Are procedures in place to ensure that correct versions of spreadsheets are being used?

Are there procedures in place for archiving and retrieving retired versions of spreadsheets?

*Other Systems*

Is an electronic document management system used, and if so, is it validated?

Is an electronic training-record database used, and if so, is it validated?

Are laboratory periodic maintenance and calibration activities scheduled and recorded by a maintenance management system, and if so, is it validated?

## 8 LABORATORY INVESTIGATIONS

CGMPs exist to not only prevent problems from occurring but also mitigate and address deficiencies when they do occur. The Laboratory Investigations sub-element is designed to systematically identify the root cause of failures, to determine how to correct the problems, and to prevent them from re-occurring in the future.

The Laboratory Investigations sub-element includes at least three individual topics. A laboratory that is in compliance with CGMPs should address each of these topics (as applicable). These topics should include (1) Laboratory Investigations-General, (2) Laboratory Investigations-Execution, and (3) Laboratory Investigations-Documentation.

These three topics are listed below in the form of possible questions an FDA inspector may ask when conducting an audit of the laboratory. The list of items under each topic is fairly comprehensive but may not be totally inclusive of all those components that may constitute the sub-element.

---

**LABORATORY INVESTIGATIONS SUB-ELEMENT**

*Laboratory Investigations-General*

Is there an SOP that defines in detail when and how laboratory investigations are conducted?
Does the SOP distinguish between OOS and deviations or atypical events?
*Does the SOP have a flowchart and/or decision tree to assist in performing laboratory investigations?*
Does the SOP have a checklist to assist in determining the root cause of the deviation or failure?
Does the checklist include review of specifics such as:

- Use of proper test methods and proper execution of the test method?
- Performance of proper calculations without mathematical error?
- Use of proper reagents, standards, and glassware?
- Execution of proper sample preparation?
- Execution of proper standard preparation?
- Analysis of proper samples?
- Execution of proper analytical technique such as mixing, shaking, centrifuging, filtering weighing, and dilution?
- Use of proper equipment?
- Use of properly qualified and calibrated equipment?
- Special considerations for proper execution of HPLC methods?
- Special considerations for proper execution of GC methods?
- Special considerations for proper execution of dissolution testing?
- Special considerations for proper execution of IR analysis?
- Special considerations for proper execution of UV/Vis spectroscopy analysis?
- Special considerations for proper execution of titrations including Karl Fischer?

Are OOS investigations handled in a manner consistent with the Barr decision and FDA guidance documents?
Does the SOP prevent release of product by continuous testing, re-testing, or re-sampling (e.g., testing into compliance)?
Does the SOP clearly define situations when re-analysis or re-testing is appropriate, and provide guidelines on how it will be executed?
Does the SOP address special circumstances such as unidentified chromatographic peaks or shifting retention times of known peaks?
Are roles and responsibilities for executing laboratory investigations clearly defined in the SOP?
Are all laboratory personnel trained in the proper execution of laboratory investigations?

*Laboratory Investigations-Execution*

**TABLE** (*Continued*)

| |
|---|
| Is supervisor immediately notified of an OOS, deviation, or atypical event? |
| Are test material (glassware, test solutions, standard solutions, etc.) retained? |
| Is equipment and instrumentation left in the same conditions as when the event that cause the investigation occurred? |
| Are investigations performed in a timely manner? |
| Are the individuals responsible for generating the OOS, deviation, or atypical event involved in the investigation? |
| Is a concerted effort made to find a root or assignable cause of all laboratory investigations? |
| Are investigations closed in a timely manner? |
| If the OOS is discovered after product release, is there a system in place to evaluate the impact of product that is in the market? |
| Is the Quality Assurance Unit integrated into the laboratory investigations process? |
| If laboratory investigations cannot be completed in their allotted time frame, is there a formal mechanism in place to extend their due date? |
| *Laboratory Investigations-Documentation* |
| Is software (e.g., tracking, trending, and reporting) used to complete laboratory investigations? |
| Has the software been validated? |
| Is there a standard report or forms that are used for documenting laboratory investigations? |
| Are investigations supported with sufficient data to include chromatograms, spectra, raw data, etc.? |
| Is there a process for implementing corrective and preventive actions upon closure of laboratory investigations? |
| Are laboratory investigations tracked and trended? |
| Are the trending reports used during annual product reviews? |
| If the root cause of the investigation is not determined, is a conscious and rational decision on the impact of continued testing made? |
| Can final investigation reports be understood from someone outside the organization and stand on its own with limited verbal explanation? |

## 9 CONCLUSION

As shown in the sections above, the laboratory control system is actually a collection of "systems within a system." This chapter has outlined seven potential sub-elements within the laboratory control system. Depending upon your individual laboratory, there may be additional sub-elements that you may identify. The intent of the questions posed for each sub-element is to encourage the reader to begin thinking of the laboratory control system as a series of interrelated sub-elements, each of which is needed for the entire laboratory to operate in a state of control. In the end, if you address the questions highlighted in the seven sub-elements listed, your laboratory will be in control and comply with the requirements of 21 CFR parts 210 and 211, the Current Good Manufacturing Practice Regulations.

## 10 GLOSSARY OF TERMS

The following terms are commonly encountered while working in a CGMP laboratory:

*21 CFR Part 11* Title 21, Code of Federal Regulations, Part 11. Part 11 established the criteria under which electronic records and signatures will be considered equivalent to paper records and handwritten signatures in manufacturing processes regulated by the FDA.

*483 (Form 483)* The designation of the FDA form which is used to capture and report observations of CGMP deficiencies related to FDA on-site audits. These observations are compiled and become part of the Facilities Inspection Report. Form 483 observations become part of the public record.

*Abbreviated New Drug Application (ANDA)* Application made to the FDA for a generic version of a branded drug. The duplicate drug must be bioequivalent to the branded version of the drug. The first company to receive FDA approval of an ANDA receives 180 days of market exclusivity for the generic drug.

*Absorption, Distribution, Metabolism, and Excretion/Toxicology (ADME/T)* The objective of ADME/T testing is to measure what happens to a compound in the human physiology. ADME/T tests are done during the preclinical stage of the drug discovery process and are a necessary part of any clinical trial, prior to filing an IND.

*Acceptance Criteria* Numerical limits, ranges, or other suitable measures used to determine the acceptability of the results of analytical procedures.

*Accuracy* Expresses the closeness of agreement between the value found and the value that is accepted as either a conventional true value or an accepted reference value. It may often be expressed as the recovery by the assay of known, added amounts of analyte.

*Action Level/Alert Level* Alert level is used to identify the point at which a parameter has drifted toward the extreme of the specified operating range. Action level is when the parameter has drifted outside of the specified operating range. Alert and action levels must be tighter than registration specifications. Alerts are reported to management and evaluated. If an action level is reached, it is reported to management and investigated, and a corrective action initiated.

*Active Pharmaceutical Ingredient (API)* Also known as drug substance. Any component that is intended to furnish pharmacological activity or other direct effect in the diagnosis, cure, mitigation, treatment, or prevention of disease, or to affect the structure of any function of the body of humans or other animals.

*Adverse Drug Reaction (ADR)* An adverse drug reaction is an undesirable effect associated with the use of a drug. It may occur as a standard part of the drug's action, or it may be unpredictable.

*Agonist* An agonist is a substance or drug that can interact with a receptor and initiate a physiological or pharmacological response characteristic of that receptor.

*Analytical Performance Characteristics* A term used by the USP, analytical performance characteristics refer to those characteristics of an analytical method that define its performance as an analytical technique. These performance characteristics include accuracy, precision, specificity, detection limit, quantitation limit, linearity, and range. These characteristics need to be considered when validating anyone of the USP method categories.

*Antagonist* An antagonist is a drug or compound that opposes the physiological effects of another. At the receptor level, it is a chemical entity that opposes the receptor-associated responses normally induced by another bioactive agent.

*Aseptic Processing* A method of producing a sterile (devoid of living organisms) product in which sterile bulk drug or raw materials are compounded and assembled with sterile packaging components.

*Assay* A laboratory test or technique to identify and/or measure the amount of a particular substance in a sample, or for determining characteristics such as composition, purity, activity, and weight. Used to determine whether compounds (drugs, chemicals, etc.) have the desired effect in a living organism, outside the organism, or in an artificial environment.

*Atypical Result* Results generated on a test article that are within specifications but are inconsistent with previous data, established trends, or other results for the same sample on test.

*Audit* An effort to determine through investigation the adequacy of and adherence to established procedures, instructions, specifications, codes, and standards or other applicable requirements as well as the effectiveness of their implementation.

*Audit Trail* An automatic feature of some computer programs or operating systems that creates a running record of all transactions.

*Batch* A specific quantity of a drug or other material that is intended to have a uniform character and quality within specified limits, and is produced according to a single manufacturing order during the same one cycle of manufacture.

*Batch Record* A record prepared for each batch of drug product or API produced that includes complete information relating to the production and control of each batch.

*Bioanalysis (Bioanalytical)* Analytical procedure(s) to quantify results of target analyte(s) in a defined biological matrix.

*Bioassay* The determination of the biological activity of a drug by observing its effect on an organism (or organ) compared to a standard preparation.

*Bioavailability* A measure of the uptake of an ingested substance by the body as assessed by its concentration in the blood. The rate and the extent of its appearance in the blood are important determinants of bioavailability.

*Bioequivalence* A scientific basis on which generic and brand name drugs are compared with one another. Drugs are bioequivalent if they enter circulation at the same rate when given in similar doses under similar conditions. Proof of bioequivalence is crucial for generic drugs and must be demonstrated in ANDAs.

*Biological* According to the FDA's CBER, a biological product is any virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, or analogous product applicable to the prevention, treatment, or cure of diseases or injuries to humans. Biological products include, but are not limited to, bacterial and viral vaccines, human blood plasma and their derivatives, and certain products produced by biotechnology, such as interferons and erythropoietin.

*Biologics License Application (BLA)* An application to the FDA for a license to market new biological products in the United States.

*Biotechnology* The industrial use of living organisms (or parts of living organisms) to produce foods, drugs, or other products. The oldest biotechnologies include fermentation and plant and animal hybridization.

*Blank* A sample or standard of a particular matrix or composition without analyte.

*British Pharmacopoeia (BP)* The authoritative, current collection of standards for UK medicinal substances and the official source of all UK quality standards. It is used by individuals and organizations involved in pharmaceutical research, development, manufacturing, and testing.

*Calibration* The demonstration that a particular instrument or device produces results within specified limits by comparison with those produced by a reference or traceable standard over an appropriate range of measurements.

*Change Control Procedure* A procedure describing measures to be taken for controlling and maintaining an audit trail when changes are made to any part of a system (e.g., standard operating procedure, test method, or specification).

*Calibration Curve* A calibration curve is a plot of standard solution concentration, on the x-axis, vs. instrument response, on the y-axis. In chromatographic analyses, calibration curves are generated by analyzing standard analyte solutions of known concentration and measuring the resulting chromatographic peak area. The resulting plot is then used to determine the concentration of unknown sample solutions containing the same analyte. This is done by measuring the unknown peak area ($y$) and using the equation for the line to solve for the concentration of the unknown ($x$). Although referred to as a "curve," it is usually a linear plot with a well-defined slope and y-intercept.

*Capacity Factor $k'$* A dimensionless quantity used to describe the retention of a compound. It is calculated by the following formula: $(t_r - t_0)/t_0$, where $t_r$ is the measured retention time of the component of interest and $t_0$ is the retention time of an un-retained component. $t_0$ is most measured at the first disturbance of the baseline in HPLC analyses. $t_r$ is measured at the peak apex. $k'$ is a normalized value for retention. Values range between 2 and 10 for acceptable chromatography.

*CBE 30 Change by Effect, 30 Days* Supplemental changes to applications that do not require prior approval by the FDA. These changes may be implemented within 30 days following submission to the FDA if the agency has no comments.

*Center for Biologics Evaluation and Research (CBER)* The FDA successor to the Bureau of Biologics concerned with biologic drugs and with the new protein and peptide drugs arising from biotechnology. According to its charter, the CBER is responsible for ensuring the following:

- The safety of the U.S. entire blood supply and the products derived from it
- The production and approval of safe and effective childhood vaccines, including any future AIDS vaccines
- The proper oversight of human tissue for transplantation

- An adequate and safe supply of allergenic materials anti-toxins
- The safety and efficacy of biological therapeutics, including an exciting new array of biotechnology-derived products used to treat diseases such as cancer and AIDS

*Center for Drug Evaluation and Research (CDER)* The successor to the Bureau of Drugs of the FDA concerned with all SVPs (Small-Volume Parenterals), LVPs (Large-Volume Parenterals), and non-biological or small-molecule drugs.

*CGMPs* Current Good Manufacturing Practices. Section 21 Code of Federal Regulations parts 210 and 211. Federal regulations that describe the minimum CGMPs for preparation of drug products for administration to humans and animals. They include methods to be used in and the facilities or controls to be used for the manufacturing, processing, packing, or holding of a drug to assure that such drug meets the requirements of the act as to safety, has the identity and strength, and meets the quality and purity characteristics that it purports or is represented to possess.

*Check Standard* A second preparation of the working standard that is analyzed as part of the system suitability run. The check standard is prepared at the same concentration as the working standard. Prior to continuing the chromatographic run, the ratios of the response factors (response factor = area/concentration) for the working standard and the check standard are calculated. RF check standard/RF working standard should normally be within $\pm 2.0\%$. This provides assurance that the working standard was prepared correctly.

*Chemistry, Manufacturing, and Controls* Known as CMC, it is the section on a BLA, IND, NDA, or ANDA describing the composition, manufacture, and specifications for drug product and its ingredients.

*Chiral Compound* Molecules that have the same chemical formula and the same structural formula but are mirror images to each other. Stereochemically speaking, they exhibit "handedness." Molecules with the same empirical formula that are not superimposable on their mirror images are chiral.

*Chromatography* Separation of a mixture of substances by size, charge, or other characteristic by allowing the mixture to partition between a moving phase and a stationary phase.

*Clinical Trial* Carefully designed investigations of the effects of investigational new drugs, medical treatments, or devices on a group of patients. There are typically three phases of clinical trials prior to the filing of an NDA, sometimes followed ongoing post-approval studies. See Phase I, Phase II, Phase III, and Phase IV.

*Compendial Test Methods* Test methods that appear in official compendia such as the United States Pharmacopoeia (USP/NF).

*Complaint* Any verbal, written, or electronic report that alleges deficiencies related to the identity, strength, quality, purity, or effectiveness of a product after it has been released for distribution.

*Compliance* A state of operations that ensures activities is following documented procedures.

*Component* Any ingredient intended for use in the manufacture of a drug product, including those that may not appear in such drug product and primary packaging components.

*Compounding* Bringing together into homogenous mix of active ingredients, excipients, and, as applicable, solvent components.

*Consent Decree* A voluntary legal agreement a drug firm enters into with the FDA for the expressed purpose of correcting deficiencies related to CGMPs.

*Computer Systems Validation* Confirmation by examining and providing objective evidence that computer system specifications conform to user needs and intended uses, and that all requirements can be consistently fulfilled.

*Contract Manufacturing Organization (CMO)* A company that offers manufacturing services, with volume capabilities ranging from small amounts for preclinical R&D to larger volumes necessary for clinical trial purposes and commercialization.

*Contract Research Organization (CRO)* A company involved in performing clinical research on a contract basis for a pharmaceutical company, research organization, or other health organization. CROs are contracted to perform some or all of the duties by the sponsor for a clinical trial; examples include monitoring the trial, enrolling patients, performing statistical analysis, and writing the protocols. By some definitions, CROs may also perform CMC development work.

*Degradation Product* A molecule resulting from a chemical change in the drug molecule brought about over time and/or the action of light, temperature, pH, water, etc. or by reaction with excipient and/or the immediate container–closure system.

*Detection Limit* The detection limit (DL) or limit of detection (LOD) of an individual procedure is the lowest amount of analyte in a sample that can be detected but not necessarily quantitated as an exact value. The LOD is a parameter of limit tests (tests that only determine if the analyte concentration is above or below a specification limit). In analytical procedures that exhibit baseline noise, the LOD can be based on a signal-to-noise ratio (3:1), which is usually expressed as the concentration (e.g., percentage, parts per billion) of analyte in the sample.

*Development Report* A report that summarizes the major stages of drug product or API development from early stages through large-scale manufacturing.

*Documentation* Any combination of text, graphics, data, audio, or video information that can be used to clearly and completely recreate an activity, event, or process. Documentation includes life cycle documents as well as records.

*Document Control System* A system for managing preparation, review, approval, issuance, distribution, revision, retention, archival, obsolescence, and destruction of life cycle documents.

*Dosage Form* The form in which the drug is delivered to the patient. Dosage forms include parenteral, topical, tablet, oral (liquid or dissolved powder) suppository, inhalational, and transdermal.

*Drug Substance* See Active Pharmaceutical Ingredient (API).

*Drug Product* The combination of API and excipients that are processed into a dosage form and marketed to the public. Common examples include tablets, capsules, oral solutions, etc. Also referred to as finished product or dosage form.

*Efficacy* Measures the power to produce, in a controlled setting such as a clinical trial, a stated effect typically attributable to a known physiologic phenomenon. It is important to derive measures of efficacy because, with appropriate statistical achievements, these data can approximate real-world effectiveness.

*Effective Date* Date by which the approved standard or procedure shall be implemented and in use. All required training must be completed prior to this date.

*Endpoint* In clinical trials, a parameter used to compare the results in different arms of the trial. Endpoints may be directly related to the condition (such as progression of the disease) or may be measurements of surrogate markers.

*European Pharmacopoeia* Official compendium of the member states of the Council of Europe, including all EC and European Free Trade Association (EFTA) countries.

*Excipient(s)* An excipient is a raw material that may perform a variety of roles in a drug product (e.g., tablet press lubricant, filler, diluent, disintegration accelerator, and colorant). However, unlike the API, which is pharmacologically active, the excipient has no intrinsic pharmacological activity.

*Extraction Efficiency* Is a measure of the effectiveness of extraction of the drug substance from the sample matrix. Studies are conducted during methods validation to determine that the sample preparation scheme is sufficient to ensure complete extraction without being unnecessarily excessive. This is normally investigated by varying the shaking or sonication times (and/or temperature) as appropriate.

*Expiration Date* The date placed on the container/labels of a drug product or API designating the time during which a batch of product is expected to remain within the approved shelf life specification if stored under defined conditions, and after which it must not be used.

*Food and Drug Administration (FDA)* The U.S. Federal Agency charged with promoting and protecting the public health by helping safe and effective products reach the market in a timely way and monitoring products for continued safety after they are in use. Founded in 1938.

*Filter Study* A comparison of filter to unfiltered solutions in a methods validation to determine whether the filter being used retains any active compounds or contributes unknown compounds to the analysis.

*Forced Degradation Studies* Studies undertaken to degrade the sample (e.g., drug product or API) deliberately. These studies, which may be undertaken during method development and/or validation, are used to evaluate an analytical method's ability to measure an active ingredient and its degradation products without interference and are an integral part of the validation of a method as being specific and stability indicating.

*Formulation* The recipe that describes the quantity and identity of API and excipients that make up a drug product. For example, a 100-mg tablet of Advil® may actually weigh 165 mg total. The formulation may include 100 mg of ibuprofen

(the active ingredient), 50 mg of starch (filler), 5 mg of talc (lubricant for the tablet press), and 10 mg of iron oxide (colorant).

*Good Laboratory Practice (GLP)* A set of rules and criteria for a quality system concerned with organizational process and the conditions under which non-clinical health and environmental safety studies are planned, performed, monitored, recorded, archived, and reported. The GLP principles have been developed to promote the quality and validity of data generated in the testing of chemicals in order to facilitate their recognition for the purposes of assessment and other uses relating to the protection of human health and the environment. U.S. GLPs are found in 21 CFR Part 58.

*Good Documentation Practices* The handling of written or pictorial information describing, defining, specifying, and/or reporting of certifying activities, requirements, procedures, or results in such a way as to ensure data integrity.

*GxP* Good [*x*] Practice. Commonly refers to GLP, GMP, and GCP (good clinical practices).

*High Performance Liquid Chromatography (HPLC)* A separation technique based on a solid stationary phase and a liquid mobile phase. Separations (into distinct bands) are achieved by partition, adsorption, or ion-exchange processes depending upon the type of the stationary phase used. Each band is then profiled, as the solvent flows through an electronic detector, typically UV, fluorescence, or refractive index. Sometimes called high pressure liquid chromatography.

*ICH* The Tripartite International Conference on Harmonization, an international organization formed to establish uniform guidance within the pharmaceutical industry. For drug development and manufacture, the ICH issues guidance such as ICH Q2A *Text on Validation of Analytical Procedures* (March 1995), which is designed to instill uniformity within the industry with respect to various drug development and manufacturing issues. The ICH is composed of industry experts who work jointly and with the FDA to develop these guidance documents.

*International Organization for Standardization (ISO)* Non-governmental organization responsible for developing international standards founded in 1947. The ISO's 13,700 standards are voluntary and market driven. The ISO 9000 series has become an international reference for quality requirements in business-to-business dealings, and the ISO 14000 standards address environmental issues.

*Investigational New Drug Application (IND)* An application to the FDA to begin clinical trials of a new drug or biologic on humans. The IND gives the plan for the study and contains formulation, manufacturing, and animal test results information.

*Identification Test* An analytical method that is capable of determining the presence of the analyte and can discriminate between closely related compounds.

*In-Process Control/Test* Checks performed during production in order to monitor and, if appropriate, to adjust the process and/or to ensure that the product meets its specifications. The control of the environment or equipment may also be regarded as part of in-process control.

*Intermediate* Any substance, whether isolated or not, that is produced by chemical, physical, or biological action at some stage in the production of a drug product or API and that is subsequently used at another stage of production.

*Internal Audit* A systematic examination conducted by an internal organizational unit to determine whether quality activities and related results comply with policies, standards, and requirements and whether practices have been implemented effectively and are suitable to achieve objectives and ensure compliance with regulatory requirements.

*IQ/OQ/PQ* Installation, Operation, and Performance Qualification. The process by which laboratory equipment is properly installed and determined to be operating within specifications for its intended use. IQ/OQ/PQ is executed via a protocol with predetermined acceptance criteria.

*Label Claim* Theoretical strength of the product as given on the marketed product label.

*Laboratory Qualification* A process where a laboratory that has demonstrated that it has the systems in place necessary to properly perform the tests being conducted.

*LIMS* Laboratory Information Management System. Any computer system that is used to collect, compile, organize, and report laboratory data. LIMS systems may also be used to calculate results as well.

*Linearity* Evaluates the analytical procedure's ability (within a given range) to obtain a response that is directly proportional to the concentration (amount) of analyte in the sample. If the method is linear, the test results are directly, or by well-defined mathematical transformation, proportional to the concentration of analyte in samples within a given range. Linearity is usually expressed as the confidence limit around the slope of the regression line. The line is calculated according to an established mathematical relationship from the test response obtained by the analysis of samples with varying concentrations of analyte. Linearity may be established for all active substances, preservatives, and expected impurities. Evaluation is performed on standards. Note that this is different than *Range* (sometimes referred to as *Linearity of Method*), which is evaluated using samples and must encompass the specification range of the component assayed in the drug product.

*LIR* Laboratory Investigation Report. An investigation of any laboratory results or observation that does not meet acceptance criteria or falls outside the expected operational parameters. Similar to an OOS investigation, but does not have to do with meeting a release specification.

*Lot* A batch or any portion of a batch having uniform character and quality within specified limits; or, in case of a drug product, a continuous process, it is a specific identified amount produced in a unit of time or quantity in a manner that assures its having uniform character and quality within specified limits.

*Matrix (Sample Matrix)* The components and physical form with which the analytes of interest are intimately associated. In the case of drug product, the matrix is the combination of excipients in which the active ingredient is diluted and formed within. For example, the matrix of a transdermal patch is an adhesive, in which the

drug substance is dissolved, fixed to a plastic backing covered by a release liner. The chemical composition and physical structure of the matrix can have a substantial effect on sample preparation and extraction of the active moiety.

*Master Production Record* A document that specifies complete manufacturing and control instructions, sampling, and testing procedures, specifications, special notations, and precautions to be followed in production of the product and assures uniformity from batch to batch by specifying the batch size, components, and quantities and theoretical yields.

*Maximum Allowable Residue* The maximum allowable residue is used to calculate the acceptance criteria for cleaning verification methods. Residue limits should be practical, achievable, verifiable, and based on the most deleterious residue. Limits may be established based on the minimum known pharmacological, toxicological, or physiological activity of the API or its most deleterious component.

*Method Development* The process by which methods are developed and evaluated for suitability of use as test methods, and as precursor to validation.

*Method Qualification* Preliminary methods validation conducted during phases 1, 2, and 3 to support the drug development process and the associated release of clinical trial material.

*Method Transfer* Moving any analytical technique (chemical or microbiological) from one site/area to another.

*Methods Validation* The process by which it is established, by systematic laboratory studies, that the performance characteristics of the analytical method meet the requirements for intended analytical applications. The FDA states in their guidance document, "Methods validation is the process of demonstrating that analytical procedures are suitable for their intended use. The methods validation process for analytical procedures begins with the planned and systematic collection by the applicant of the validation data to support analytical procedures."

*Method Verification* The process by which compendial methods are determined to be suitable for analysis of a given test article by a given laboratory. As cited in 21 CFR Part 211.194(a) (2), method verification is used for USP/NF compendial methods or those compendia (and other recognized references such as the AOAC book of methods) that have documented evidence that the methods have been validated. At a minimum, this involves sample solution stability, specificity, and intermediate precision.

*New Drug Application (NDA)* An application to the FDA for a license to market new drug in the United States that sponsor companies submit NDAs after completing clinical trials on a new drug.

*OOS Investigation* The systematic and planned search for the root cause that generated an out-of-specification result. An OOS investigation should include formal reporting and a description of corrective and preventative actions taken.

*OOS Result* Out-of-Specification Result. An examination, measurement, or test outcome that does not comply with the specification or predetermined acceptance criteria.

*Percent RSD (% RSD)* Percent Relative Standard Deviation. A common expression and measure of the relative precision of an analytical method for a given set of measurements. Percent RSD is calculated by dividing the standard deviation for a series of measurements by the mean of the same sets of measurements and multiplying by 100, i.e., % RSD = (σn − 1/mean) × 100. Large percent RSDs for a series of measurements indicated significant scatter and lack of precision in the technique.

*Personnel Qualification* The combination of education, training, and/or experience that enables an individual to perform assigned tasks.

*Pharmacokinetics (PK)* The movement of drugs within biological systems as affected by uptake, distribution, elimination, and biotransformation.

*Pharmacology* The study of how drugs produce their effects. Pharmacology relies on knowledge of physiology, biochemistry, molecular biology, and other scientific disciplines.

*Phase I* Initial safety studies in humans. May include as few as 10 subjects, often in healthy volunteers, and includes PK, ADME/T, and dose escalation studies to determine some side effects. Usually open label.

*Phase II* Following initial safety (Phase I) testing, a drug is tested for efficacy, typically blind, randomized trials, in which a control group receives a placebo. Phase II testing may last from several months to two years. Phase II trials involve 100–300 subjects with the disease or condition of interest. Includes PK, dose ranging, safety, and efficacy.

*Phase III* Following Phase II testing, a drug is tested in a large-scale setting (several hundred to several thousand patients) to determine effectiveness, benefits, and the range of possible adverse reactions. Most Phase III studies are randomized and double blinded and typically take several years. Usually, two well-controlled studies are necessary to establish efficacy. Once the Phase III trials are successfully completed, a pharmaceutical company can request FDA approval for marketing the drug, by filing a New Drug Application (NDA).

*Phase IV* Following FDA approval and marketing, drug companies may conduct further studies on their products. These post-approval studies have several objectives, including comparing the drug with other drugs already in the market, monitoring the drug's long-term effectiveness, and determining additional potential uses for the drug.

*Pre-Approval Inspection (PAI)* An inspection of an establishment that performs manufacturing steps in an approved BLA or NDA and for which the applicant has submitted a supplement for significant manufacturing change or other change that ordinarily requires on-site review of the change.

*Process Impurity* Any component of the drug product resulting from the manufacturing process that is not the chemical entity defined as the drug substance or an excipient in the drug product.

*Placebo* A formulation containing all ingredients of a drug product, except the active ingredient for which the method is being developed.

*Precision* Expresses the closeness of agreement (degree of scatter) between a series of measurements obtained from multiple aliquots of a homogenous sample under the

prescribed conditions. The precision of an analytical procedure is usually expressed as the percent relative standard deviation. According to the FDA and the ICH, precision may be considered at three levels, namely:

*Repeatability* Refers to the use of the analytical procedure within a laboratory by a single analyst, on a single instrument, under the same operation conditions, and over a short interval of time. This is sometimes referred to as method precision.

*Intermediate Precision* Refers to variations within a laboratory as with different days, with different instruments, by different analysts, and so forth. Formally known has ruggedness.

*Reproducibility* The measure of the capacity of the method to remain unaffected by a variety of conditions such as different laboratories, analysts, instruments, reagent lots, elapsed assay times, and days – more succinctly, the use of the method in different laboratories. Reproducibility is not part of the expected methods validation process. It is addressed during technical transfer of the method to different sites.

*Prospective Validation* Validation conducted prior to the distribution of either a new product, or product made under a revised manufacturing process, where the revisions may affect the product characteristics.

*Protocol* An approved documented experimental design that, when executed, will demonstrate the ability of the subject method to perform as intended. Formal methods validation studies require a protocol. The protocol must have pre-assigned and approved acceptance criteria for each stage of the validation. The protocol may be a stand-alone document or may reference the methods validation SOP for specific details.

*Q* The amount of dissolved active ingredient specified in the monograph, expressed as a percentage of the labeled content of the dosage form, obtained during dissolution testing. For example, a tablet may have a specification stating that 85% of the active must be dissolved in 30 minutes of dissolution testing using USP apparatus II (paddles). In this case $Q = 85\%$. Also, a nefarious character in the Star Trek: The Next Generation TV series.

*Quality Agreement* The procedures established to ensure that a product is manufactured or a clinical trial is performed in compliance with the appropriate standards and regulatory requirements, and that the process or results are properly documented.

*Quality Assurance Unit* The Quality Assurance Unit serves the role of the Quality Control Unit as defined in 21 CFR 211.11. In this document, only the compliance function of the Quality Unit is addressed, not the testing functions. In the past, there has been some confusion with respect to Quality Assurance and Quality Control. CGMPs now generally recognize QA = compliance, and QC = testing.

*Qualification* Action of proving and documenting that equipment or ancillary systems are properly installed, work correctly, and actually lead to the expected results. Qualification is part of validation, but the individual steps alone do not constitute process validation.

*Quality System* A group of interrelated activities representing an integrated approach to philosophy and practices of manufacturing APIs and drug products to assure safety, identity, strength, purity, and quality.

*Quality Unit* An organizational unit independent of production which ensures that the manufacture, testing, storage, and distribution of drug products, active pharmaceutical ingredients, and components are performed in compliance with regulatory requirements and conformance to company policies and industry practices. See Quality Assurance Unit.

*Quantitation Limit* The quantitation limit (QL) or limit of quantitation (LOQ) of an individual analytical procedure is the lowest amount of analyte in a sample that can be quantitatively determined with suitable precision and accuracy. The quantitation limit is a parameter of quantitative assays for low concentrations of compounds in sample matrices and is used particularly for the determination of impurities and/or degradation products. It is usually expressed as the concentration (e.g., percentage and parts per million) of analyte in the sample. For analytical procedures that exhibit baseline noise, the LOQ is generally estimated from a determination of signal-to-noise ratio (10:1) and may be confirmed by experiments.

*Quarantine* The status of materials isolated physically or by other effective means to preclude their use pending a decision on their subsequent disposition.

*Range* The interval between the upper and lower concentrations (amounts) of analyte in the sample (including these concentrations) for which it has been demonstrated that the analytical procedure has a suitable level of precision, accuracy, and linearity. Range is normally expressed in the same units as test results (e.g., percent and parts per million) obtained by the analytical method. Range (sometimes referred to as *Linearity of Method*) is evaluated using samples and must encompass the specification range of the component assayed in the drug product.

*Raw Data* Raw data are defined as the original record of measurement or observation. Raw data may include, but are not limited to, printed instrument output, electronic signal output, computer output, hand-recorded numbers, digital images, hand-drawn diagrams, etc. Raw data are proof of the original measurement or observation and, by definition, cannot be regenerated once collected.

*Raw Material* Any ingredient intended for use in the production of intermediates, APIs, or drug products.

*Reference Standard* A reference standard is a highly purified compound that is well characterized. It is used as a reference material to confirm the presence and/or amount of the analyte in samples.

*Related Compounds* Related compounds are categorized as process impurities, degradants, or contaminants that may be found in finished drug products.

*Repeatability* The variation experienced by a single analyst on a single instrument. Repeatability does not distinguish between variation from the instrument or system alone and from the sample preparation process.

*Reporting Limit* The level, at or above the LOQ, below which values are not reported (e.g., reported as "<0.05% for a reporting limit = 0.05%). The reporting limit may be defined by ICH thresholds.

*Reprocessing* Introducing a previously processed material that does not conform to standards or specifications, back into the process, and repeating a step or steps that are part of the established manufacturing process.

*Resolution* A measure of the efficiency of the separation of two component mixtures. In chromatographic analyses, a resolution of >1.5, which means two peaks are separated from each other all the way to the baseline, is desirable.

*Response Factor* A measure of the signal generated by a detector normalized to the amount of analyte present. In HPLC it is usually the peak area for a given component (the response) divided by the concentration or mass that generated that response.

*Retain Sample* Reserve samples. An appropriately identified sample that is representative of each lot or batch of drug product or API that is stored under conditions consistent with the product labeling, in the same container–closure system in which the product is marketed or in one that is essentially of the same characteristics. Used for testing that may be involved in analyzing complaint samples.

*Relative Response Factor (RRF)* The ratio of the response factor of a major component to the response factor of a minor peak. This allows the accurate determination of a minor component without the need for actual standards.

*Relative Retention Time (RRT)* The normalization of minor peaks to the parent peak in a chromatogram. The RRT of the parent will be 1.0. Peaks eluting before the parent will have RRTs < 1.0. Peaks eluting after the parent will have RRTs > 1.0.

*Retrospective Validation* Validation of a process for a product already in distribution based upon accumulated production, testing, and control data.

*Revalidation* The process of partially or completely validating a method or process after changes or modifications have been made to the manufacturing process, analytical methodology, equipment, instrumentation, or other parameter(s) that may affect the quality and composition of the finished product. The USP specifically sites changes in synthesis of drug substance; changes in the composition of the drug product; and changes in the analytical procedure.

*Robustness* The measure of the ability of an analytical method to remain unaffected by small but deliberate variations in method parameters (e.g., pH, mobile phase composition, temperature, instrument settings); provides indication of its reliability during normal usage. Robustness testing is a systematic process of varying a parameter and measuring the effect on the method by monitoring system suitability and/or the analysis of samples. It is part of the formal methods validation process.

*Ruggedness* A date term, now commonly accepted as intermediate precision. See Intermediate Precision.

*Selectivity* Selectivity is the ability of the method to separate the analyte from other components that may be present in the sample, including impurities. Determination of selectivity normally includes analyzing placebo, blank, media for dissolution, dilution solvent, and mobile phase injections. Also, no chromatographic peaks, such as related compounds, should interfere with the analyte peak, or internal standard peak if applicable. Selective = separate and shows every component in the sample.

*Signal-to-Noise* In chromatography the measure of average baseline noise (e.g., peak-to-peak) to the signal given by an analyte peak. S/N calculations are performed when determining the LOD and the LOQ.

*Specification* The quality standards (e.g., tests, analytical procedures, and acceptance criteria) provided in an approved application to confirm the quality of the drug substances, drug products, intermediates, raw materials, reagents, and other components including in-process materials.

*Spiking* The addition of known amounts of a known compound to a standard, sample, or placebo, typically for the purpose of confirming the performance of an analytical procedure or the calibration of an instrument.

*Spiked Placebo* Preparation of a sample to which known quantities of analyte are added to placebo material. Performed during validation to generate accurate and reproducible samples that are used to demonstrate recovery from the sample matrix.

*Specificity* The ability to assess unequivocally the analyte in the presence of components that may be expected to be present, such as impurities, degradation products, and excipients. There must be inarguable data for a method to be specific. Specific = measure only the desired component without interference from other species that might be present; separation is not necessarily required.

*Stability* Refers to the physicochemical condition of a parenteral, biologic, or shelf life of other drugs. Certain drugs must pass USP or CFR stability tests. Manufacturers must have documentation of the potency of products under labeled storage conditions. Product stability is determined through execution of a formal stability protocol, which requires storage of the drug product, under controlled environmental conditions, in its planned marketed product containers for periods up to three years.

*Stability Indicating Methodology* A validated quantitative analytical procedure or set of procedures that can detect the changes with time in the pertinent properties (e.g., active ingredient, preservative level, or appearance of degradation products) of the drug substance and drug product.

*Stability-Indicating Assay* An assay that accurately measures the component of interest (the active ingredient(s) or degradation products) without interference from other degradation products, process impurities, excipients, or other potential interfering substances.

*Stability Indication Profile* A set of procedures or assays that, collectively, detect changes with time, although may not do so individually.

*Standard Operating Procedures (SOPs)* The description of activities necessary to respond to normal and abnormal situations in the operation system. SOPs may include troubleshooting checklists, lists of personnel to contact, etc. They should also describe normal operation, maintenance, and cleaning of the system, as well as normal operating parameters. In the laboratory, all analytical methods are required to be documented in SOPs that are commonly referred to as standard test methods (STMs).

*Standard and Sample Solution Stability* The stability of standards and samples is established under normal benchtop conditions, under normal storage conditions, and sometimes in the instrument (e.g., an HPLC autosampler) to determine if special

storage conditions are necessary, for instance, refrigeration or protection from light. Stability is determined by comparing the response and impurity profile from aged standards or samples to that of a freshly prepared standard and to its own response from earlier time points. Note that these are short-term studies and are not intended to be part of the stability indication assessment or product stability program.

*Stressed Studies* See Forced Degradation Studies.

*Supplemental New Drug Application (sNDA)* Application submitted for an already-approved NDA for any changes in packaging, labeling, dosages, ingredients, or new indications.

*System Suitability* System suitability is the evaluation of the components of an analytical system to show that the performance of a system meets the standards required by a method. A system suitability evaluation usually contains its own set of parameters; for chromatographic assays, these may include tailing factors, resolution, and precision of standard peak areas, and comparison to a confirmation standard, capacity factors, retention times, theoretical plates, and calibration curve linearity.

*Tailing Factor* A measure of peak asymmetry. Peaks with a tailing factor of $>2$ are usually considered to be unacceptable due to difficulties in determining peak start and stop points, which complicates integration. Tailing peaks are an indication that the chromatographic conditions for a separation have not been properly optimized.

*Technology Transfer* The transfer of a process or method including demonstration of equivalence according to predetermined criteria between the receiving and transferring sites.

*Test Method* An approved, detailed procedure describing how to test a sample for a specified attribute (e.g., assay), including the amount required, instrumentation, reagents, sample preparation steps, data generation steps, and calculations used for evaluation.

*Theoretical Plates* A dimensionless quantity used to express the efficiency or performance of a column under specific conditions. A decrease in theoretical plates can be an indication of HPLC column deterioration.

*Transcription Accuracy Verification (TAV)* The process where the transcription of data from one location to another is confirmed by a second party. Important with methods validation reports which summarize results in tables derived from raw data.

*United States Pharmacopoeia (USP)* A non-governmental, not-for-profit organization that promotes the public health by establishing standards to ensure the quality of medicines and other health care technologies. These standards are developed by a publicly involved process and are accepted worldwide. The USP provides standards for more than 3400 prescription and non-prescription drugs, nutritional and dietary supplements, veterinary drug standards, and health care products. These standards are published in the United States Pharmacopoeia and National Formulary (USP-NF).

*USP <1225> Category I* One of four method categories for which validation data should be required. Category I methods include analytical methods for quantitation of major components of bulk drug substances or active ingredients (including preser-

vatives) in finished pharmaceutical products. Category I methods are typically referred to as assays.

*USP <1225> Category II* One of four method categories for which validation data should be required. Category II methods include analytical methods for determination of impurities in bulk drug substances or degradation compounds in finished pharmaceutical products. These methods include quantitative assays and limit tests.

*USP <1225> Category III* One of four method categories for which validation data should be required. Category III methods include analytical methods for determination of performance characteristics (e.g., dissolution, drug release).

*USP <1225> Category IV* One of four method categories for which validation data should be required. Category IV methods include analytical methods used as identification tests.

*Validation* A documented program that provides a high degree of assurance that a specific process, method or system will consistently produce a result meeting predetermined acceptance criteria.

*Validation Characteristics* See Analytical Performance Characteristics.

*Validation Parameters* See Analytical Performance Characteristics.

*Validation Protocol* A prospective plan that, when executed as intended, produces documented evidence that a process, method, or system has been properly validated.

*Validation Report* A summary of experiments and results that demonstrate the method is suitable for its intended use, approved by responsible parties.

*Verification* The act of reviewing, inspecting, testing, checking, or otherwise establishing and documenting whether items, processes, services, or documents conform to specified requirements.

## 1 INTRODUCTION

Among the many experimental techniques available for the identification of solid forms, including polymorphs, solvates, salts, cocrystals and amorphous forms, X-ray powder diffraction (XRPD) stands out as a generally accepted "gold standard." While this does not mean that XRPD should be used to the exclusion of other experimental techniques when studying solid forms, X-ray diffraction (XRD) has applications throughout the drug development and manufacturing process, ranging from discovery studies to lot release. The utility of X-ray diffraction becomes evident when one considers the direct relationship between the measured X-ray diffraction pattern and the structural order and/or disorder of the solid. XRPD provides information about the structure of the underlying material, whether it exhibits long-range order as in crystalline materials, or short-range order as in glassy or amorphous materials. This information is unique to each structure—whether crystalline or amorphous—and encoded in the uniqueness of the XRPD pattern collected on a well-prepared sample of the material being analyzed.

One must draw a distinction between crystalline materials, which give rise to XRPD patterns with numerous well-defined sharp diffraction peaks, and glassy or amorphous

**TABLE 1 Types of Solid Forms Described by the Wunderlich (1) Classification System**

| Solid Form | Translation | Orientation | Conformation |
|---|---|---|---|
| Crystal | Long range | Long range | Long range |
| Condis crystal (glass) | Long range | Long range | Short range |
| Plastic crystal (glass) | Long range | Short range | Short range |
| Liquid crystal (glass) | Short range | Long range | Short range |
| Amorphous (glass) | Short range | Short range | Short range |

materials whose XRPD patterns contain typically three or less broad maxima (X-ray amorphous halos). In practice, using XRPD, one can usually measure a sequence of progressively more disordered crystalline materials that ultimately result in glass. A classification system has been proposed by Wunderlich (1), Table 1, to describe the type of structural order and molecular packing present in molecular organic solid forms using three order parameter classes: translation, orientation, and conformation.

Solid forms of a given molecule exhibiting long-range crystalline order (e.g., polymorphs, solvates, co-crystals, and salts) can be identified and characterized using XRPD by their unique combination of order parameters. Amorphous solid forms do not exhibit any long-range order but are identifiable and characterized by their unique local molecular order, apparent in the X-ray amorphous diffraction pattern (2).

Knowing that X-ray powder diffraction is sensitive to structural order, some of its typical applications in the analysis of solid-state properties of a drug substance or product include:

- Identification of existing forms of the active pharmaceutical ingredient (API).
- Characterization of the type of order present in the API (crystalline and/or amorphous).
- Determination of physical and chemical stability.
- Identification of the solid form of the API in the drug product.
- Identification of excipients present in a drug product.
- Monitoring for solid form conversion upon manufacturing.
- Detection of impurities in a drug product.
- Quantitative analysis of a drug product.

Where appropriate data are available, XRPD analysis can determine the solid-form structure and crystal-packing relationship among individual molecules in the solid. This information is essential to the understanding of solid-state chemistry of drugs and important from the regulatory perspective.

## 2 X-RAY DIFFRACTION THEORY

When dealing with organic samples, a common simplification called the first Born approximation (3,4) is useful in explaining the X-ray diffraction process. Solid forms

***FIGURE 1*** *A simple periodic array of molecules with a single orientation and conformation and constant spacing, d.*

of organic materials are expected to interact weakly with incident X-rays (generally true provided the crystallite size is not too large). This means that the amplitude of doubly and multiply scattered radiation will be very small and negligible when compared to the singly scattered radiation (4). In the presence of crystal defects, grain boundaries or disordered systems (i.e., typical laboratory samples and not large, perfect single crystals), the multiply scattered radiation becomes even less significant.

Respecting the limits of these assumptions, we can model the diffraction process as a Fourier transform of the electron density within the sample. Figure 1 shows a simple example containing a periodic array of molecules separated by a constant spacing, $d$, and with a single orientation and conformation. While each atom is considered a point source of scattering (5), the molecules themselves can be reduced to point sources of scattering under the assumption that the electron density distribution of a collection of atoms is the sum of the electron density distributions attributed to individual centered atoms (4). Note that atoms in a molecule are not necessarily the same as isolated, free atoms, though they are often approximated as such. The latter approximation allows us to substitute values for the Fourier transform of electron density of each individual atom using the tables of atomic scattering factors (6).

During the diffraction process, the ordered arrangement of point scattering centers in real space produces a set of diffraction events in reciprocal space corresponding to sharp peaks. A spacing of $d$ between the point centers (molecules) in real space will correspond to a peak spacing of $2\pi/d$ in reciprocal space (also called $Q$-space). This simple Fourier identity, illustrated in Fig. 2, will apply to any molecular-translational order existing within a solid form (4).

Therefore, diffracted peak positions can be expressed in terms of $d$-space, $Q$-space or, most commonly, $2\theta$, the angle between diffracted and undeviated X-ray waves (5).

***FIGURE 2*** *A Fourier transform relates a periodic array of molecular point scattering centers in real space to a family of diffraction peaks in reciprocal space.*

Bragg's law can be used to relate the X-ray half-scattering angle $\theta$ to the aforementioned spacing parameter, $d$, as seen in Eq. 1.

$$n\lambda = 2d\sin\theta \tag{1}$$

The parameter $\lambda$ is the wavelength of the incident X-ray radiation, with a typical value of approximately 1.54 Å for a Cu X-ray radiation source. $n$ is an integer and can best be understood through the explanation of why Bragg's law holds. Consider a case of many parallel scattering planes—each of which is a collection of previously introduced point-scattering centers—reflecting incoming X-ray radiation of wavelength $\lambda$ at the angle $\theta$, as seen in Fig. 3 (5). The two diffracted waves in Fig. 3 will interfere with each other either constructively (adding together to produce stronger peaks) or destructively (subtracting from each other to some extent), depending on whether they are in phase or out of phase, respectively (4). Since the wave diffracted by the bottom plane in Fig. 3 travels a greater distance (greater by exactly $a + b$) than the wave diffracted by the top plane, that extra distance must be equal to an integer multiple of $\lambda$ for points to remain in phase and total constructive reinforcement to

***FIGURE 3*** *Bragg's law for parallel planes.*

occur between the scattering from these planes (Eq. 2).

$$n\lambda = a + b \tag{2}$$

$a$ and $b$ can be expanded using the law of sines as $\sin\theta = a/d = b/d$. Simple substitution then transforms Eq. 2 into Bragg's law (1). The integer $n$ refers to the order of the diffraction. For additional readings on X-ray diffraction theory, see for example References (4–8).

## 3 X-RAY DIFFRACTION EXPERIMENTAL PROCEDURES

XRPD patterns display diffracted intensity as a function of the experimental parameter $2\theta$ (angle between diffracted and undeviated X-ray waves). Intensity is typically expressed in counts or counts per second while peaks are listed as positions in $°2\theta$ or $d$-spacings (usually measured in Å or nm).

### 3.1 Crystalline Materials

For materials exhibiting long-range (crystalline) order, XRPD patterns will contain sharp peaks, Fig. 4, whose shape and width will depend on the type of instrument on which the data were collected. Measurement ranges for crystalline materials depend on the type of study. For example, in a common application of XRPD—small-molecule polymorphism study—1–40°$2\theta$ is a typical measurement range used, since

***FIGURE 4*** *XRPD pattern of crystalline itraconazole.*

peaks above approximately 30°2$\theta$ become too numerous and overlapped to be useful in differentiating between polymorphs. When working with large molecules (e.g., biologicals), it is advantageous to measure to as low an angle as allowed by the geometry of the instrument (approximately 0.5°2$\theta$ is achievable in typical laboratory settings with modern instruments, sub 0.5°2$\theta$ using a synchrotron or with a dedicated small-angle scattering instrument). Certain computational methods may require measurements to significantly higher 2$\theta$ angles, up to 100°2$\theta$.

Collection time varies per application but, for polymorphism studies, good patterns of crystalline material on modern instruments can be obtained in 2–10 min. In high throughput configurations for well plates, collection times of less than a minute per pattern can readily be achieved. Depending on the instrument geometry and application, 2–20 mg of crystalline sample may be required, and the sample can be reused afterwards as XRPD is typically non-destructive.

XRPD suffers from two common sample-related effects that can play a significant role when characterizing or identifying crystalline material. Ideal XRPD samples have large numbers of randomly oriented crystallites. The reproducibility of an XRPD pattern is dependent on particle-orientation statistics, while preferred orientation limits the degree to which a pattern accurately represents the structure, as opposed to a particular sample preparation. For those reasons, one must assess the particle statistics and degree of preferred orientation before one can be confident the peak identifications made from a particular pattern are representative of the material.

The effect of non-random (preferred) orientation of crystallites in a sample is to increase the relative intensities of some peaks and decrease the relative intensities of others. The variation in peak intensity is proportional to the degree of preferred orientation. In extreme cases, it can cause peaks to disappear completely while exaggerating otherwise faint peaks. Even in mild cases, a different set of relative intensities would result from diffractometers with different sample geometries.

Poor particle statistics are displayed by samples where a relatively small number of crystallites contribute to the integrated XRPD patterns. Since the small population of large crystallites cannot represent all possible orientations, the measured relative intensities are not reproducible. Irreproducible peak intensities lead to the expectation that the pattern may differ dramatically if the same experiment was repeated on a different sample of the same material even using the same diffractometer.

Both preferred orientation and poor particle statistics can be reduced to some extent in laboratory samples by spinning the sample in a holder (9, 10). Diffractometers allow the sample to be spun around one or two axes. In addition, a simple way of assessing the degree of preferred orientation or particle statistics in a sample is to analyze it on two different diffractometers with different spinning geometries. A summary of methods to minimize preferred orientation can be found in References (11–14). Bish (5) includes a detailed discussion on sample preparation and related problems.

## 3.2 X-Ray Amorphous Materials

In the case of X-ray amorphous (disordered, glassy or amorphous) materials, there will be no sharp peaks observed in the XRPD pattern, only broad halos (Fig. 5).

***FIGURE 5*** *XRPD pattern of amorphous itraconazole.*

Nevertheless, as we shall see later on, it is possible to extract structural information from these types of patterns using computational methods. Many of the computational methods used to analyze disordered materials require that the data are collected over a broad range, typically from 1 to 100°$2\theta$. Furthermore, because the signal-to-noise ratio in X-ray amorphous patterns is typically poor, longer collection times are often used. 30–60 min is not uncommon for a single pattern. Finally, a greater amount (50–100 mg) of amorphous sample is typically warranted to obtain a good XRPD pattern.

XRPD patterns of both crystalline and X-ray amorphous materials contain some experimental artifacts, for example, instrument-background functions, sample-holder fingerprints, incoherent (Compton) scattering, polarization and Lorentz effects, and air scatter (5). The relatively low signal generated from X-ray amorphous samples means those artifacts will represent a much greater portion of the overall diffracted intensity. Therefore, computational methods used to analyze X-ray amorphous materials (15–17) are very sensitive to experimental artifacts and care must be taken to minimize their presence. Instrument intensity-correction functions can be determined using known standards and computationally modeled thereafter. Sample holders that produce significant X-ray scattering of their own in the relevant regions (e.g., glass capillaries) should be avoided when working with amorphous materials. Instead, samples can be sandwiched between thin polymer films with low X-ray background (e.g., Etnom®). Given the chemical formula of the material, Compton scattering can be calculated from atom-scattering tables (6) and subtracted from the overall signal. Air scatter can be largely eliminated using custom-built enclosures for a helium atmosphere.

***FIGURE 6*** *The effects of experimental artifacts on amorphous X-ray patterns. Both patterns were collected from the same sample of amorphous nifedipine. The top pattern was collected from approximately 10 mg of material packed in a glass capillary under ambient conditions. The collection time was 5 min. The bottom pattern was collected from approximately 100 mg of material sandwiched between two thin sheets of Etnom® film in a He-purged enclosure. The collection time was 1 h.*

Figure 6 shows an X-ray amorphous pattern of nifedipine collected on a standard instrument with no special considerations and the sample packed in a glass capillary, compared to the same sample collected on a specially configured instrument using a low background sample holder, He atmosphere, and longer collection time. Note the patterns in this figure have not been offset but normalized to top intensity. As seen in the bottom pattern of Fig. 6, the low angle air scatter contribution is largely eliminated through the use of He. Furthermore, the broad glass scattering around $25°2\theta$ which causes a shift in the position of the second amorphous halo in the top pattern is not evident in the bottom pattern. Typically, in screening applications, no more than a few milligrams of material are available, resulting in patterns where the glass/air scatter signal overwhelms the signal from the material itself and little structure is evident.

Certain types of analyses involving crystalline materials (e.g., quantitative studies or indexing) may also benefit from careful experimental setups but the most common applications (i.e., polymorph detection or identification (18)) generally do not require the specialized setups or longer collection times used for amorphous materials.

## 3.3 Instrumentation

Laboratory X-ray diffractometers typically consist of an X-ray source, sample chamber and detector. The most commonly used X-ray source in laboratory experiments with organics is Cu, though instruments typically allow different sources to be used with some configuration. Slits and optics are used to focus the incident and diffracted radiation on the sample and detector, respectively. Specimens usually can be rotated to alleviate some of the intensity artifacts discussed earlier. Detectors can be point, line or area, with the latter offering advantages in both speed of acquisition and ability to assess the particle statistics and preferred orientation in a sample through examination of Debye rings (19). Synchrotron sources are sometimes used for specialized measurements to collect high quality data. Detailed descriptions of X-ray instrumentation can be found, for example in Reference (5).

The alignment of a diffractometer is maintained through the use of calibration standards, such as silicon, to verify the position calibration (5). Regular calibrations are accepted industry practice (cGMP), with the frequency of calibration ranging from every $X$ number of samples to set time periods (e.g., daily), depending on how much data one is willing to risk invalidating due to a failed calibration. When a silicon standard is used, the Si 111 peak position is typically verified using a short scan in the appropriate region (around 28.4°$2\theta$). Other standards may be used, for example, to verify low angle alignment.

Diffractometers can typically be operated in either reflection or transmission configurations. Reflection is by far the more common and also referred to as Bragg-Brentano geometry (Fig. 7). In reflection measurements, incoming X-rays are "reflected" off the sample surface and focused by the instrument optics onto the detector. Errors due to sample transparency to X-rays are common for organic samples (5,14). The X-rays penetrate many atomic layers below the surface meaning the average diffracting surface lies somewhat beneath the surface of the sample. This type of error can lead to peak position errors in measured patterns of as much as a tenth of a degree. Therefore, low absorbing samples are often prepared as thin films using

***FIGURE 7*** *Bragg-Brentano diffractometer geometry.*

a low background holder, to reduce the penetration effect. Displacement errors arise from the difficulty of preparing samples such that the surface of the sample is level with the surface of the holder (where the instrument is focused). Sample-displacement errors can result in significant, systematic shifts in measured peak positions, on the order of several tenths of a degree in particularly bad cases. Experience in preparing samples such that they are level with the surface of the holder is the only solution to this problem, although computational methods can be used to shift the pattern and correct peak positions, where the error is recognized. A further limitation of reflection measurements is the inability to measure to very low angles—typically $2.5°2\theta$ is a practical limit—making this type of measurement less useful for the analysis of large molecules which are expected to have peaks in the $0–2.5°2\theta$ range.

Transmission mode analysis overcomes many of the limitations of reflection mode when carefully configured. In transmission measurements, the incident X-rays pass through the sample and are diffracted not only on the surface but throughout the sample. This type of analysis is possible for organics due to their relative transparency to X-rays. The sample no longer needs to be level with the holder but thickness of the sample is important and can cause peak displacement errors (when the sample is too thick). Transmission configurations generally allow lower angle measurements than reflection, making them useful for large molecules. However, it becomes essential that the holder containing the sample is as X-ray transparent as possible, because its "fingerprint" will be part of the X-ray pattern collected on each sample. Disposable, low background thin polymer films are commonly used to hold the sample in transmission measurements. In addition, it is common practice to regularly collect blanks (X-rays of the holder material itself) to ensure its signature does not change between different lots. Nevertheless, the extra effort required to operate instruments in transmission mode is well worth the improvement in data quality, especially when working with X-ray amorphous materials.

## 4 APPLICATIONS OF X-RAY DIFFRACTION IN DRUG DEVELOPMENT AND MANUFACTURING

XRD has a broad range of applications in various stages of drug development and manufacturing. This section will address many of the common XRPD uses from a practical standpoint. In the broadest terms, these applications can be divided between API characterization and identification. While there is some overlap in both categories, the former is more commonly applied during drug development (before the drug is on the market) while the latter is directed more toward manufacturing, regulatory aspects and intellectual property.

### 4.1 API Characterization

Guidelines from regulatory authorities regarding the need for characterization of a drug substance under development have been clearly stated. Below is an example relating to the issue of polymorphism (20):

"Polymorphic forms of a drug substance can have different chemical and physical properties, including melting point, chemical reactivity, apparent solubility, dissolution rate, optical and mechanical properties, vapor pressure, and density. These properties can have a direct effect on the ability to process and/or manufacture the drug substance and the drug product, as well as on drug product stability, dissolution, and bioavailability. Thus, polymorphism can affect the quality, safety, and efficacy of the drug product."

While there are a number of methods to characterize polymorphs of a drug substance (21), the two broadly accepted methods of providing unequivocal proof of polymorphism recognized by the above source are single crystal X-ray diffraction and X-ray powder diffraction (20). Other techniques (e.g., thermal or spectroscopic methods) can be helpful in further characterizing drug products but only X-ray provides the necessary structural information to uniquely identify different polymorphs. Therefore, in early drug development, X-ray powder diffraction is often used as a primary experimental technique and a means of differentiating between the experimentally generated materials. Fully characterizing any material requires the use of complementary techniques (thermal or spectroscopic) but X-ray is typically done first because it is fast, non-destructive, requires little material, and provides the necessary structural information.

Synchrotron X-ray diffraction has frequently been used to characterize pharmaceutical materials in applications where additional sensitivity not provided by laboratory X-ray diffractometers may be required (e.g., crystallization monitoring (22,23)). The tradeoff is the greater expense and time investment typically associated with such measurements. Since such applications tend to be specialized, this section will focus primarily on laboratory XRPD methods.

***4.1.1 Qualitative Analysis of Materials (Phase Identification)*** Every structurally different crystalline material will exhibit a unique XRPD pattern upon analysis (14). Therefore, the use of XRPD for phase identification was recognized early and remains the most common application of XRPD to pharmaceuticals. This so-called qualitative analysis typically refers either to the initial characterization of material previously not analyzed by XRPD or to the identification of a phase or phases in a sample of material by comparison to reference patterns. Reference patterns are previously collected XRPD patterns of the same material. Where available, XRPD patterns calculated from, for example, single crystal structures can be substituted but one should remember that the temperature at which the pattern is calculated can have a significant effect on the calculated XRPD profile. When dealing with mixtures of phases, qualitative analysis can provide an estimate of the relative proportions of different phases in the sample, usually based on the comparison of peak intensities for characteristic peaks of the different phases. Due to sample artifacts such as preferred orientation and poor particle statistics, this type of analysis should never be confused with quantitative analysis of mixtures, addressed later in this chapter. Databases of known XRPD patterns for various pharmaceutical materials are published annually by the Centre for Diffraction Data (ICDD) and the Cambridge Crystallographic Data Centre (CSD).

XRPD patterns are typically compared by overlaying and aligning the data from different samples. This procedure is typically done electronically, either using the software provided by the XRPD instrument vendor or using custom-developed software. The primary assessment might include determining whether each sample is X-ray amorphous or crystalline based on the absence or presence of crystalline peaks, respectively. When comparing XRPD data of crystalline samples, one notes any differences in peak positions (to within a certain precision, e.g., 0.1 °$2\theta$ (24)) which correspond to structural differences between the samples. Intensities are generally not relied upon for qualitative analysis due to previously mentioned instrument and sample artifacts, although they have to be used to some degree to allocate the peak positions (based on local maxima).

It is not uncommon for two patterns to share some but not all of the peak positions. This can be a coincidence or it can be due to one of the samples being a mixture of multiple phases, including the phase in the other sample. Experience and data from complementary experimental techniques are needed to resolve such ambiguous cases. It should also be noted that, at higher $2\theta$ values, peaks of most organic materials become considerably overlapped and determining their exact positions becomes difficult. Therefore, free-standing peaks at low angles are the primary means of differentiating structures and XRPD data above approximately 30 °$2\theta$ are rarely useful for qualitative analysis.

Figure 8 shows XRPD patterns of two crystalline polymorphs of sulfamerazine. The patterns in Fig. 8 were collected from material crystallized in glass capillaries during a polymorphism screen. A polymorphism screen is typically run early in the

***FIGURE 8*** *Two polymorphs of sulfamerazine. Patterns offset for clarity.*

drug development process to identify and (partially) characterize the different polymorphs of a drug substance. Assuming XRPD was the first analytical technique used on the samples, the data in Fig. 8 could be used to make a qualitative assessment regarding the probable nature of the material generated during crystallization experiments. Therefore, one could designate the first of the patterns crystalline "Pattern A" and the other crystalline "Pattern B," noting the sharp peaks and lack of diffuse halos as a sign of crystallinity and the structural differences, as evidenced by the different peak positions in each pattern. There is insufficient information at this stage to designate either pattern as a polymorph of the material (e.g., they could be a solvate, hydrate, or a mixture of two or more polymorphs). However, it is clear that both materials are crystalline and structurally different. Further characterization using for example, thermal methods (TGA, DSC) would confirm these materials are not solvates or mixtures but actual polymorphs and aid in determining the thermodynamically stable polymorph. XRPD provides information about the structure of materials, not thermodynamics, although variable-temperature XRPD has been used to study changes in structure at different temperatures.

One can envision a large number of different crystallization experiments (using different solvents or conditions) performed on the API, some possibly in automated fashion, with the resulting material characterized initially by XRPD. This is in fact a common approach to polymorphism, salt, and cocrystal screening and perhaps the most common application of XRPD in the drug development process. The latter two screens are usually performed when the polymorph(s) of the drug candidate itself are not sufficiently bioavailable, in an effort to produce a formulation that addresses the bioavailability problem. An XRPD pattern is taken of the API and the guest material (e.g. acid) and the mixture of the two. If a salt or cocrystal was formed, the XRPD pattern of the mixture should be more than just a sum of the reference patterns of the API and the guest.

Therefore, the first application for XRPD during drug development is typically to identify the materials generated using different experimental methodologies, often in automated high throughput screening environments (25–27). To simplify this pattern recognition problem that often involves hundreds or thousands of experimental data sets per screen, people have developed various computational approaches to recognize, sort, and classify unknown XRPD patterns, either through comparison to a known database of materials (28) or simply within the experimental set of unknown patterns (18, 29, 30). The latter often uses an approach called hierarchical clustering (31, 32).

XRPD data are often catalogued in databases using the so called Hanawalt system (33–34). In this system, the data are stored as $d$ versus $I/I_{max}$ pairs. The use of $d$-space eliminates the need to specify the radiation source wavelength and allows comparison between laboratories using different instrumentation. A similar system is often used for intellectual property filings, as discussed later in this chapter.

However, as we shall see in following sections, there is considerable structural information available in a typical XRPD pattern that can be used to characterize the material. Making use of this information usually requires high quality laboratory data and the use of advanced computational methods.

***4.1.2 Structural Analysis of Crystalline Forms*** XRPD patterns of crystalline materials have sharp peaks due to constructive interference of diffracted radiation. As mentioned previously, XRPD patterns can be used to identify particular substances by comparison with reference patterns, analogous to the use of fingerprints to identify people. For example, the experimental XRPD pattern of Mannitol in Fig. 9 (bottom pattern) compares best with the simulated pattern of the beta form (second pattern) indicating that the sample is likely form beta, and not form alpha or delta. The positions of the reflections in XRPD patterns are functions of the size and shape of the crystallographic unit cell. Reflection intensities are functions of the atomic positions within the unit cell. A variety of instrumental and sample preparation artifacts influence the intensities, and to a lesser extent, the positions of the reflections. A first step in the further characterization of an XRPD pattern of a crystalline sample is to rationalize the reflection positions using a process called indexing.

*4.1.2.1 Indexing* Indexing is the process of determining the size and shape of the unit cell given the peak positions in a diffraction pattern. The term gets its name from the assignment of Miller index labels to individual peaks. For most applications, the index labels are less important than are the unit cell length and angle parameters that provide the link between crystal properties and the diffraction pattern.

***FIGURE 9*** *Comparison of simulated (top three) and measured (bottom) XRPD patterns of Mannitol. The legend provides ICDD reference codes and form designations for the simulated patterns.*

Indexing plays a role in single crystal and powder diffraction pattern analysis, but there are qualitative differences between indexing single crystal and powder diffraction data. For single crystal diffraction, reflections are recorded as a function of the three-dimensional orientation of a crystal relative to the incident radiation. Each reflection in single crystal diffraction corresponds to a solution of the Laue equations, or equivalently the vector form of the Bragg equation. For powder diffraction, the (ideally) isotropic distribution of particle orientations leads to cylindrical symmetry in the diffracted radiation. Therefore, each reflection in powder diffraction corresponds to a solution of the scalar form of the Bragg equation (35). As a result of the loss of information regarding the relative orientations of diffracting crystallites, indexing of XRPD data is more challenging than single crystal diffraction data.

There are a variety of methods available for indexing XRPD patterns, some of which are in the public domain and others that are sold commercially. Examples include ITO (36), TREOR (37), N-TREOR (38), singular value decomposition (39), X-CELL (40), and DICVOL (41). The methods differ in their methods for identifying and refining potential solutions, ability to determine low symmetry solutions, efficiency, and sensitivity to extraneous and/or missing peaks. Development of novel methods and refinement of existing methods continues to be an area of active research. When applying these automated methods, it is important to be aware that multiple solutions can appear to adequately index a XRPD pattern. These degenerate solutions are called lattice metric singularities (42). In such cases, it is common practice to accept the higher symmetry solution unless there is other evidence supporting the lower symmetry solution.

Successful XRPD indexing serves several purposes. If all of the peaks in a pattern are indexed using a single unit cell, this is strong evidence that the sample contains a single crystalline phase. Given the indexing solution, the unit cell volume may be calculated directly. The difference in molar volume between an anhydrous crystal form and the molar volume of hydrates, solvates, and co-crystals can be useful for determining their stoichiometries. If the chemical composition of a crystal is known, then indexing provides the means of determining very accurate true densities. Indexing is also a robust description of a crystalline form. Common practice is to characterize forms using a list of XRPD peak positions for selected intense peaks, but the intensities of individual peaks are sensitive to changes in temperature, defect density, and preferred orientation effects as a result of sample preparation. Also, the positions of peaks are sensitive to temperature, strain, and changes in hydration state. Although unit cell parameters change as a result of these effects, the changes are less pronounced when comparing indexing solutions than when comparing peak lists based on particular selection criteria. Indexing can be used to show that a XRPD pattern is consistent with the structure of a crystal determined via single crystal diffraction. Also, indexing is a preliminary step for other analyses including structure determination from XRPD data and Rietveld refinement.

*Data* Not all XRPD patterns are amenable to indexing. XRPD patterns must have sufficient signal-to-noise and peak resolution to provide enough peak positions to uniquely define the indexing solution. Signal-to-noise can be improved by eliminating sources of diffuse scattering such as glass sample holders and by collecting the pattern

for a longer time. Peak width is a convolution of instrumental and sample contributions. Therefore, a diffractometer with adequate monochromatization is necessary, but not sufficient to ensure good peak resolution. Samples containing nanoscale crystalline regions or defective crystals display broadened peaks in their XRPD patterns. In the extreme, these broadened peaks can overlap and produce a pattern that appears to contain only amorphous halos as discussed elsewhere in this chapter.

Wilson showed that centrosymmetric crystal structures (those containing an inversion center) are more likely to have very weak and very strong reflections than are non-centrosymmetric crystal structures (lacking an inversion center) which tend to have a narrower distribution of peak intensities (43). Ordered crystals containing only one enantiomer (or diastereomer) of a chiral molecule cannot crystallize in space groups with mirror planes, glide planes, or inversion centers since those operations change the chirality of the molecule. Therefore, crystals containing non-chiral molecules or racemic mixtures of chiral molecules may adopt a centrosymmetric structure whose XRPD pattern has a large fraction of very weak reflections. Since these weak reflections are often important for successful indexing of the XRPD pattern, care should be taken to optimize peak sensitivity when collecting XRPD data for indexing, particularly for non-chiral molecules or racemic mixtures. This can be accomplished by reducing sources of background scattering and by increased collection times, for example.

The bottom XRPD pattern in Fig. 9 is an experimental XRPD pattern of Mannitol, form beta. Since Mannitol is chiral, it is expected to crystallize in a non-centrosymmetric structure and the corresponding XRPD pattern should have relatively few extremely weak or strong reflections. There is relatively little diffuse background scattering and the signal-to-noise ratio appears to be very good in the pattern. Also, the peaks are quite sharp leading to good peak resolution. All of these observations suggest that the XRPD pattern is amenable to indexing under the assumption that the pattern represents a single crystalline phase.

*Results* A successful indexing solution for the Mannitol XRPD pattern from Fig. 9 is illustrated in Fig. 10. The bars in Fig. 10 correspond to positions of allowed reflections based on Bragg's Law. All of the observed peaks in the XRPD pattern are indexed by one or more of the allowed reflections. Also, there are relatively few allowed reflections that are not observed. In some cases, the reflections are too weak to be evident at the scale shown in Fig. 10, but are evident using an expanded scale. If the allowed reflections did not account for all of the observed reflections, then the solution

***FIGURE 10*** *Indexed XRPD pattern of Mannitol form beta. Green bars indicate allowed reflections based on the unit cell dimensions and assigned space group $P2_12_12_1$ (no. 19). Dashed bars indicate extinct reflections.*

would have been rejected as unable to fully describe the observed pattern. If there were a large number of allowed but unobserved peaks, then the solution would be rejected in favour of a smaller volume and/or higher symmetry solution. Since the illustrated solution falls into neither category, it is accepted as a good description of the observed pattern. This confirms that the XRPD pattern is of a single crystalline phase.

There are some allowed reflections, marked with dashed bars in Fig. 10, that are not observed. These systematic extinctions are the result of space group symmetry elements of the contents of the unit cell. Systematic extinctions are the result of centered unit cells, screw axes, and/or glide planes. Rules indicating which reflections are extinct based on their Miller indices are tabulated (35). Given the observed systematic extinctions in a pattern, an extinction symbol may be assigned (44). In the illustrated case, the extinction symbol ($P2_12_12_1$) corresponds to only one space group, $P2_12_12_1$ (no. 19). In many other cases, there are two or more space groups corresponding to the observed extinction symbol and additional analysis is needed to fully determine the space group.

The solution illustrated in Fig. 10 is orthorhombic with length parameters given in Table 2. Given the length parameters, the unit cell volume is readily calculated. The number of asymmetric units in the unit cell for a given space group is tabulated in Reference (44). For space group $P2_12_12_1$ there are four asymmetric units in the unit cell ($Z = 4$). Assuming that there is one Mannitol molecule per asymmetric unit ($Z' = 1$), then the molar volume and density are readily calculated. The density is a bit higher than typical organic molecules, but is as expected for sugars such as Mannitol. A reasonable density confirms that the correct number of molecules per asymmetric unit was assumed.

Having successfully indexed the XRPD pattern, determined the extinction symbol, and calculated the density, the analysis of peak positions in the Mannitol XRPD pattern is complete. Additional information regarding the Mannitol sample can be derived from the peak shapes and intensities using the Rietveld method.

**TABLE 2 Indexing Results and Derived Quantities**

| Substance and Form | Mannitol Form Beta |
|---|---|
| Composition | $C_6H_{14}O_6$ |
| MW (amu/molecule) | 182.172 |
| Family and space group | Orthorhombic $P2_12_12_1$ (no. 19) |
| $a$ (Å) | 8.6790 |
| $b$ (Å) | 16.8980 |
| $c$ (Å) | 5.5502 |
| $\alpha$ (deg) | 90 |
| $\beta$ (deg) | 90 |
| $\gamma$ (deg) | 90 |
| $V$ (Å$^3$) | 813.65 |
| $Z'$ (molecules/unit) | 1 |
| $Z$ (units/cell) | 4 |
| $V/Z$ (Å$^3$/unit) | 203.41 |
| $\rho$ (g/cm$^3$) | 1.487 |

*4.1.2.2 Rietveld Analysis* The Rietveld method is a computational tool for extracting structural and microstructural information about a crystalline solid from its powder-diffraction pattern. This computational method was pioneered by Hugo Rietveld in the late 1960s (45, 46). The ability to obtain structural information from polycrystalline materials from which a crystal suitable for single-crystal analysis was either unavailable or practically impossible to obtain was a significant achievement. Initially the method was mostly used to refine the atomic positions and lattice parameters of crystal structures. Use of the Rietveld method proliferated with the increased accessibility of digital data in the 1980s and is now routinely used for quantitative analysis of phase mixtures for a wide range of materials and applications from cement and minerals to pharmaceuticals. This method is also used to characterize crystal defects and the microstructural properties of polycrystalline solids, such as preferred orientation, microstrain, and crystal size.

The Rietveld method computes a powder pattern using information describing the crystal structure and the instrumental technique used to collect the diffraction pattern. An iterative algorithm refines the structural and instrumental parameters used in the computation to minimize the difference (residual) between the observed and calculated diffraction intensity at each scattering angle ($2\theta$). The success of a Rietveld analysis depends on building an appropriate model for the algorithm so the best fit (global minimum) to the experimental pattern can be efficiently discovered while avoiding false minima. Many freeware computer programs available for Rietveld analysis are listed and described on the website (47); many programs are also commercially available. To set up a model for a system of interest and obtain reliable information, each program requires a skilled user with understanding of diffraction theory and experiment. A recommended way to learn and assess the reliability of a Rietveld program is by refining patterns of well-characterized powders. $\alpha$ $Al_2O_3$ NIST SRM 676 is a very good standard because it has no preferred orientation, two refinable atomic positions determined by single-crystal analysis (48), and two lattice parameters. The accuracy of the measured intensity and $2\theta$ combined with the skill of the Rietveld analyst and the accuracy of the Rietveld refinement algorithm determines the accuracy of the refined parameters. The applicable theoretical corrections used to compute the diffraction pattern for a particular data-collection technique require the user to judiciously construct the appropriate models (49, 50).

The minimum information needed to calculate a diffraction pattern is the atomic positions, space group, and lattice parameters of the crystal structure. The Rietveld program calculates the position and intensity of the diffraction peaks and assigns them a $2\theta$-dependent profile determined by the instrumental model. The parameters describing the profile are obtained from the results of a Rietveld analysis of a pattern of NIST SRM 660a LaB6 profile standard. This standard can also be used to check the accuracy of the lattice-parameter refinement and to refine the wavelength intensity ratio if more than one X-ray wavelength was used for data collection. For example, the ratio of Cu $K\alpha 2$ to $K\alpha 1$ is $\sim 0.5$ and can vary several hundredths depending on the type and alignment of the monochromator of the instrument used to collect the powder pattern. Standardizing the profile function allows microstrain and size (51) to be more

accurately refined as well as improving the fit of the calculated pattern to the experimental pattern.

Several quantitative and qualitative ways of assessing the "goodness of fit" between the experimental and calculated patterns are available. The qualitative assessment is a careful visual examination of the fit and the residual intensity. Visual assessment is essential and compliments the quantitative measures of the fit. The quantitative measures of the fit include the weighted pattern residual ($R_w$) and the ratio of $R_w$ to the expected residual ($R_w/R_{exp}$). This ratio indicates how close the fit is to the theoretically best residual calculated using the number of data points in the observed pattern, the number of refined variables, and the uncertainty of the observed intensity intrinsic to counting photons.

The refinement is usually done in several stages (52) with only some of the refinable parameters being refined in each stage. The scale factor for the incident-beam intensity is always refined, and the background is usually refined in the first stage. The background is best minimized in the experimental pattern by use of antiscatter slits and helium; reducing background also improves the detection limit. Background is usually modeled with a polynomial and, if the background cannot be adequately fit, it can be artificially minimized by subtracting an appropriate blank pattern collected with identical collection parameters as the specimen of interest. Subsequent stages depend on the goal of interest. None of the refinable parameters will usually be refined well the first time; therefore, several iterations are used to find the global minimum.

A successful Rietveld refinement requires the user to know if the pattern of interest displays artifacts from inadequate orientation statistics (OS) and preferred orientation. These artifacts affect relative peak intensities and can generate significantly inaccurate structure refinements. If preferred orientation is well understood, it can be corrected by a variety of models available in many Rietveld programs. OS artifacts are manifest in random fluctuations of relative intensity for each preparation of the sample and cannot be corrected. The spiky peaks generated by OS artifacts can be difficult to detect by visual examination of the one-dimensional XRPD pattern. Fortunately, they can be readily detected by collecting a two-dimensional pattern with an area detector. If the Debye rings in the two-dimensional pattern are spotty, then OS is a potential problem depending on how the pattern of interest is collected. Both PO and OS artifacts can be practically eliminated by collecting the pattern in transmission geometry using a Gandolfi spinner and by comminution of the sample. Unfortunately comminution is often not a viable option because many samples, especially organics, are susceptible to stress-induced phase transformation.

We provide an example of the limitations of refining a pattern displaying a slight amount of PO. Rietveld refinement using Maud (version 1.999) was applied to a pattern of β mannitol collected with a laboratory diffractometer in transmission geometry. To correct PO we used a March-Dollase model on the 130 hkl (Fig. 11). The atomic positions were compared to those from a single-crystal structure determination by Kaminsky et al. (53). The thermal parameters were bound to be the same for all atoms and set to be isotropic; hydrogen was not included. Without using PO corrections, the fit to the measured pattern was poor (Fig. 12).

***FIGURE 11*** *Overlay of a Rietveld refinement of $\beta$ mannitol with $R_w = 7.19\%$* and *$R_w/R_e = 1.6$* used to investigate the use of spherical harmonics to facilitate the refinement of the lattice parameters and thermal factor.

| C3-C4 | 1.523 (2) | 1.515 (16) | −0.008 | 1.555 | 0.032 |
| C4-C5 | 1.539 (2) | 1.592 (14) | 0.053* | 1.618 | 0.079 |
| C5-C6 | 1.521 (2) | 1.552 (16) | 0.031 | 1.569 | 0.048 |
| C1-O1 | 1.425(2) | 1.416 (17) | −0.016 | 1.485 | 0.053 |
| C2-O2 | 1.440 (2) | 1.443 (16) | 0.016 | 1.444 | 0.017 |
| C3-O3 | 1.433(2) | 1.390 (17) | −0.042 | 1.431 | −0.001 |
| C4-O4 | 1.448(2) | 1.434 (15) | −0.004 | 1.356 | −0.082* |
| C5-O5 | 1.445(2) | 1.439 (16) | 0.011 | 1.461 | 0.033 |
| C6-O6 | 1.436(2) | 1.431 (18) | 0.004 | 1.460 | 0.033 |
| Standard deviation | | | 0.026 | n/a | 0.040 |
| Sum | | | 0.080 | n/a | 0.284 |

*Maximum deviation.

The bond distances, Table 3, from our refinement had a 0.04 Å standard deviation relative to the single-crystal values and a maximum absolute error as high as 0.08 Å. This uncertainty is ten times larger than the uncertainty of the single-crystal bond distances and slightly higher than those refined by Botez et al. (54) using a pattern collected with a synchrotron. Our bond distances also have a positive bias. These relatively high uncertainties reflect the intensity inaccuracies from not completely correcting the PO. The inaccuracies of atomic positions will increase as the magnitude of PO and OS artifacts increase. The calculated bond angles also will be more significantly more uncertain than the reliable single-crystal values.

The magnitude of thermal displacements above those commonly measured by single-crystal analysis indicates the amount of static-displacement defects in the crystal. The refined thermal parameter (B) was 2.4 $Å^2$, and the single-crystal values for carbon and oxygen ranged from 1.64 to 2.81 $Å^2$. This result indicates the $2\theta$-dependent intensity corrections provided by the Debye-Scherrer geometry and the curved position-sensitive detector models are reasonably accurate. The intensity fluctuations from slight PO are not expected to significantly affect the thermal parameter if enough of the pattern was refined, but, depending on the magnitude of the PO artifacts, a reasonably accurate B value might not always be obtained unless an accurate PO correction is applied.

The orthorhombic lattice parameters were refined to $a = 8.6790$ Å, $b = 16.8980$ Å, and $c = 5.5502$ Å, and the zero offset was 0.0004°. These lattice parameters are within 0.01% of those refined by Botez et al. (54). The negligible offset indicates the diffractometer was very well aligned.

The beginning Rietveld analyst must have a good understanding of experimental and theoretical diffraction physics and the Rietveld model to assess the goodness of fit. The β mannitol example described here demonstrates a fairly good fit to the observed

pattern using PO corrections does not necessarily mean the refined parameters are reliable and accurate; the bond distance and angles must be compared to known ranges from reliable single-crystal determinations to see if the results are reasonable. Values of bond distance and angle for moieties on organic molecules can be found in the Cambridge Crystal Structure database. Although patterns containing intensity artifacts can be analyzed using Rietveld analysis to provide useful structural information, the use of appropriate data-collection techniques is always the best way to obtain the most reliable results.

***4.1.3 Structural Analysis of Disordered Crystalline Forms*** Highly crystalline forms of APIs are preferred in the drug development process because of their high level of purity and resistance to physical and chemical instabilities under ambient conditions (34). Unfortunately, most organic crystals are generally imperfect, containing different types of defects in the structure of the crystal lattice (4). The defective regions in a crystal introduce disorder into what is otherwise an ordered system, and correspond to sites with higher levels of energy in the solid (55). In many cases, defects can eventually lead to the formation of glass or amorphous (supercooled liquid) materials. Defects are typically formed through kinetic processes, for example, milling or dehydration, as opposed to thermodynamic processes. Whereas defects can offten be reversed, the formation of amorphous material creates a different solid state that can agglomerate or recrystallize into a different crystalline form. Pharmaceutical interest in the study of defects arises from the demonstrated role that these high energy sites can play in affecting a number of important physical and chemical phenomena. The presence of defects can, for example, produce higher dissolution rates (56, 57), greater chemical instability (58, 59), altered mechanical properties (60–62), and enhanced hygroscopicity (63, 64).

XRPD combined with computational methods can be used to study crystalline defects (4, 15), even quantitate kinetic disorder parameters (e.g., crystal strain). Random defects within a crystal structure will generate diffuse X-ray scattering similar to X-ray amorphous scattering, though with halo positions and widths that are typically different from those measured from the amorphous (supercooled liquid) phase (15). This rule can be broken when defects in the material form a kinetic glass but it is possible to monitor the agglomeration of defects starting with perfect crystals all the way through glass, using XRPD. Such a study was reported in Reference (15) and is summarized below as an example application of XRPD to the study of crystalline defects.

In this study, defects were introduced into Raffinose pentahydrate through dehydration over time. XRPD measurements were taken at regular time intervals, Fig. 13, to monitor per cent crystallinity (65) and total diffraction methodology was used to model both the coherent long range crystalline contributions and incoherent short range disorder components together as a single system (66, 67). Rietveld methods were used for structure modeling (68, 69) and to track the structural phase changes in crystalline material. In addition, methods built around the use of the Pair Distribution Function (PDF) (8, 11, 70–75), $G(r)$ in Eq. 3, were employed to confirm the Rietveld results. Finally, it was shown that the introduction of defects through

***FIGURE 13*** *XRPD patterns collected in transmission mode for raffinose pentahydrate dried at 60° C under vacuum for (from bottom to top): 0, 2, 5, and 8 h, respectively.*

dehydration of an organic crystal hydrate eventually leads to the formation of amorphous material.

$$G(r) = 4\pi r[\rho(r) - \rho_0] \tag{3}$$

Where $\rho_0$ is the average number density of the structure and $\rho(r)$ is the atom pair density for X-ray scattering (76) (Eq. 4).

$$\rho(r) = \left(\frac{1}{4}\pi r^2\right) \sum_{p,q} \left(\frac{f_p f_q}{\langle f \rangle^2}\right) \delta(r - r_{pq}) \tag{4}$$

The terms in Eq. 4 include $f_{p,q}$, the individual atomic form factors; $\langle f \rangle$, the mean atomic form factor of the structure; and the distance $r_{pq}$, corresponding to the atom pair separation. $\rho(r)$ represents the probability of finding an atom pair separated by the distance $r$, weighted by the atomic form factors and averaged over all atom pairs in the structure. The calculation needs to be evaluated over a crystal structure large enough to give the atom pair relationships for a distance of interest.

The PDF is a generally useful computational tool when analyzing X-ray amorphous or disordered systems. PDF analysis unlocks information present (but not obvious) in XRPD patterns, providing a measure of inter-atomic distances that define a solid form (70). From these distances, one can draw conclusions regarding the relationship between ordered and disordered forms of a material. By convention (71),

***FIGURE 14*** *PDF traces of crystalline (lighter, with many peaks) and amorphous (darker, with few initial peaks) felodipine. The crystalline sample shows long-range order as evidenced by peaks in the PDF up to and exceeding 100 Å. The amorphous sample shows only short-range order with PDF peaks disappearing after approximately 20 Å. Note that both samples have similar short-range order with peaks in the PDF overlapping below 10 Å.*

the PDF trace is typically plotted as distance (in Å) vs. (weighted) probability of finding two atoms with that separation. Peaks in the PDF correspond to inter-atomic distances that are common to the material in question, with the product of the peak area and distance giving the number of atom units with that specific separation. Figure 14 illustrates a PDF trace of amorphous felodipine superimposed against a PDF trace of crystalline felodipine. Both traces show similar short-range order (below 10 Å) but whereas the amorphous trace has no peaks in the PDF trace above approximately 20 Å (and therefore no long-range order), the crystalline trace contains peaks up to and exceeding 100 Å (indicating long-range order). Differences between defective crystalline (X-ray amorphous) and amorphous (supercooled liquid) materials can be seen in the PDFs calculated from XRPD data (15).

***4.1.4 Structural Analysis of Organic Amorphous Materials*** Amorphous organic solids, also referred to as disordered systems (77, 78), are characterized by a lack of long-range order that is observed in crystalline structures (2). They are often described as supercooled liquids, turned solid by the removal of thermal energy or a solvent without inducing crystallization (65, 78). Many of the early stage drug candidates currently under development exhibit very poor aqueous solubility (2, 79).

Higher molecular weights than were common in the past and greater hydrophobicity are thought to contribute to the decrease in aqueous solubility of organic compounds. With data to suggest that the dissolution rate is the rate-limiting step in oral absorption, it is expected that reduced solubility will lead to reduced oral bioavailability (80).

Amorphous organic compounds tend to have significantly higher initial aqueous solubilities (non-equilibrium) and dissolution rates as well as greater compressibility and different hygroscopicity, as compared to crystalline forms of the same compound (65, 81). Therefore, in compounds where the crystalline forms are poorly soluble, the amorphous form often presents an attractive formulation option (82). Dozens of APIs and excipients currently on the market are listed as being amorphous (65). Because crystalline forms are more thermodynamically stable than amorphous forms, there is a driving force for crystallizing the amorphous state. Therefore, amorphous materials are inherently unstable (both physically and chemically) and, once crystallized, the material loses the solubility advantage provided by the amorphous form. The inherent instability coupled with a lack of developed characterization tools has limited the commercial potential of working with amorphous materials at present (65, 83).

A common method used by formulation scientists to overcome the instabilities associated with amorphous materials is to prepare a composition of the amorphous API with pharmaceutically acceptable excipients that provide a barrier to crystallization of an amorphous drug product upon storage. Such compositions are often referred to as "dispersions" or "solid dispersions." Stabilizers are often selected from a variety of polymers, a commonly used one being polyvinylpyrrollidone (PVP). Intimate mixing (mixing at the molecular level) between such excipients and the amorphous API is an important factor in compositions resistant to crystallization (84). To provide a barrier to structural changes, the excipient needs to be intimately mixed (e.g., in a solution) with the API, which is often difficult to accomplish or even identify.

As noted earlier, XRPD is a useful technique in the analysis of amorphous materials. In its simplest application, XRPD is used to identify X-ray amorphous materials and classify them separately from crystalline materials (18). It can also be used to further differentiate between (supercooled liquid) amorphous material and kinetic glassy material (15, 85) or to monitor the conversion of crystalline material into amorphous material upon processing (e.g., grinding) (85) (Fig. 15). In the latter application, note the steady peak broadening and loss of intensity at higher angles in the XRPD patterns, Fig. 15, as the material becomes progressively disordered. However, some materials may immediately collapse into a binary amorphous-crystalline mixture and eventually pure amorphous material, without any broadening of the crystalline peaks that would be indicative of disorder in the crystalline phase (85).

Finally, in the analysis of multi-component amorphous mixtures, XRPD along with computational methods (16) have emerged as techniques that can be used to identify the so-called "miscible" dispersions, as compared to the phase separated physical mixtures where intimate mixing was not achieved. XRPD is often accom-

***FIGURE 15*** *Monitoring of cryo-grinding experiments on piroxicam form II using XRPD. Bottom-to-top, starting pattern, after 20, 40, 60, 90 min of grinding, respectively.*

panied by the use of complementary experimental techniques in this type of amorphous mixture analysis. Traditionally, thermal methods such as DSC have been used to measure glass transition temperatures when evaluating miscibility (86) and, while those methods have been shown to have limitations (16), their use is still recommended when analyzing amorphous mixtures (in addition to XRPD).

An example of this type of XRPD and computational analysis was reported in Reference (16). Solid dispersions of three different systems were analyzed initially using thermal measurements. Glass transition temperatures were identified from thermal data. For the system where two glass transition temperatures were identified, phase separation was indicated. The other two systems had a single glass transition temperature, suggesting miscibility and therefore stability to crystallization. XRPD data were collected on all three systems and the patterns were then analyzed using computational methods. Linear combinations of measured XRPD patterns and calculated PDFs were used to model the systems to determine the level of interaction between the two components in each system. The conclusions derived from thermal data were confirmed by XRPD for two of the three systems. However, the third system was identified as a so-called nano-suspension with domain sizes smaller than the resolution of thermal methods. Therefore, a prediction was made that this system is in fact phase separated despite the single glass transition temperature, and would re-crystallize. This prediction was confirmed elsewhere in the literature (87).

***FIGURE 16*** *XRPD patterns of, top-to-bottom, amorphous PVP, a solid dispersion of PVP and felodipine (70% PVP, 30% felodipine by weight), and amorphous felodipine.*

Figure 16 shows example XRPD patterns of a pharmaceutically acceptable excipient (PVP, top pattern), amorphous drug product (felodipine, bottom pattern), and a solid dispersion of the two (70% PVP and 30% felodipine by weight, middle pattern). Despite the lack of long-range order (and therefore crystalline peaks), one can observe clear differences in the structure of these amorphous materials from these XRPD patterns, using the position and width of the two broad halos in each pattern. For example, the second halo in the dispersion is located in between the second halos for the excipient and the drug product, suggesting it is a mixture of the two materials. Additional computational analysis could be applied (16) to determine the level of miscibility of the two components in the dispersion.

***4.1.5 Characterization of Multi-Component Mixtures*** A common application for X-ray powder diffraction is in the characterization of multi-component mixtures. The technique is highly effective when used for this application provided the materials are structurally different (88) and fall within the limit of detection of XRPD. With good laboratory instrumentation and sample preparation methods and typical counting times, the limit of detection for XRPD can be on the order of 2–3% by weight, or even lower when detecting the presence of crystalline materials in an amorphous-crystalline mixture. In multi-component crystalline mixtures the limit of detection can become significantly worse, especially if the component being detected has no unique peaks as compared to

the other components in the mixture. The detection of low levels of amorphous material mixed with a predominately crystalline sample can be difficult and is a subject of ongoing research (65). XRPD can also be used to quantify the amount of (crystalline or amorphous) component in the mixture as the diffracted intensity in the pattern is related to the weight percentage of the component in the mixture.

*4.1.5.1 Characterization of Crystalline Mixtures (Quantitative Analysis)* Quantitative analysis of crystalline mixtures typically refers to the determination of the relative amounts of different phases in a sample containing multiple phases (i.e., in a mixture), using experimental XRPD data. In broad terms, quantitative methods can be separated into those requiring the use of internal or external standards and ones based around the use of the full diffraction pattern (5,11, 14, 89, 90). The application of standards to this problem is not new, dating back to the 1930s (91). When using standards, it is essential to work with a randomly oriented fine powder specimen to avoid problems with preferred orientation or poor particle statistics and to be confident that the sample is representative of the material being analyzed (5, 14). In addition, there are a number of structure, instrument, and measurement-sensitive factors (14) that affect quantitative analysis.

The internal standard method (92, 93) (also called the RIR method, for reference intensity ratio) is the most general and the most commonly used of any XRPD quantitative phase analysis methods in the past. It requires that a known weight percentage of a standard material be homogeneously mixed with the sample whose phase composition one is trying to determine. The method is based on dividing the intensity of a line (peak) of the phase whose ratio in the composition is being determined by the intensity of the line for the internal standard used. As such, it is important to choose an internal standard that has peaks that do not overlap with any found in the mixture itself. Examples of standards include corundum, silicon, and SRM 676 ($Al_2O_3$) (5). The latter is particularly good at minimizing preferred orientation problems. For a detailed discussion on the RIR method see for example, (5, 14), in recent years it has been increasingly replaced by full pattern methods because of difficulties in ensuring random orientation of all components in the mixture.

The full pattern methods can be traced to quantitative work performed on cements in the 1960s (94–98). The same principles apply to pharmaceuticals with some modifications, the most important of which is the need to normalize the total diffracted intensity across different patterns before using the full pattern method. The simplest of such full pattern methods rely on fitting entire observed or calculated patterns of reference materials to an observed pattern of the mixture (5, 99). If not previously available, XRPD patterns of the reference (standard) materials must be first collected, meaning one must know the composition of the mixture beforehand. The references must be analyzed under the same conditions and instrumental settings as the mixture. When possible, the instrumental background and noise should be removed by data processing (100). Provided the same sample preparation techniques were used to

make the reference materials and the mixture(s), sample artifacts should not present as big a problem as for internal standard methods as the full pattern methods do not rely on single peaks. The weighted sum of the selected reference patterns is fit using least-squares minimization (e.g., (101)) to the unknown mixture. In this procedure, each point in the pattern is treated as an independent observation and a single weight is applied to each pattern, giving its ratio in the mixture. The best calculated fit is reported along with the weights used to obtain this pattern (5, 98, 99).

A second commonly used full pattern quantitative method is based on the use of the Rietveld method (5, 14, 102). In this method, the refinement is done by minimizing the sum of weighted, squared differences between measured and calculated intensities at every $2\theta$ position in the pattern. The Rietveld method does require the knowledge of the crystal structure for every component (of interest) in the mixture. This method is applicable even in the presence of overlapping peak lines and is less sensitive to preferred orientation problems. However, the requirement to have at least approximate crystal structures of every component can be problematic for APIs under development. Some examples of Rietveld applications to quantitative analysis include (103–105). Freely available software, for example, TOPAS (106) or GSAS (107), can be used for Rietveld quantitative analysis.

Finally, novel quantitative approaches using full pattern fitting are still an active area of research. Recent example include References (89, 108).

*4.1.5.2 Characterization of Crystalline-Amorphous Mixtures (Per cent Crystallinity)* Degree (or per cent) of crystallinity is perhaps the most common quantitative application of XRPD in the drug development process. When the amorphous phase is present or suspected, XRPD can be used to characterize the material and determine the ratio of crystalline to amorphous material in the sample. Most X-ray methods used for this purpose are based on total sample scattering (i.e., scattering from both the amorphous and crystalline phases). In addition, the total diffracted area in each measurement needs to be normalized between samples to account for example, weight or absorption differences across samples. Once the patterns are normalized, per cent crystallinity can be easily calculated as a fraction of crystalline content in the total diffracted intensity measured from a sample (109). Several methods exist to estimate the crystalline content in an XRPD pattern (65, 110):

i. Measuring the integrated peak area under the crystalline peaks and dividing by the X-ray intensity scattered by the entire sample (65). This is a common approach that works well except when many overlapping crystalline peaks are present. Examples of this type of analysis can be found in, References (110–122).
ii. Measuring the maximum intensity of a subset of characteristic peaks (109). This method can only be applied if all the samples are analyzed under the same conditions, there is no peak broadening due to disorder or particle size issues, and a reproducible ratio of intensity can be demonstrated for the chosen peaks across multiple samples. Typically, the use of internal standards is recommended for this method (65,109) to ensure the above conditions are met. Such

internal standards can include lithium fluoride, silicon metal powder, or zinc oxide. A variation on this method uses peak area rather than height (123). Examples of these types of studies include References (123–129).

iii. Quantification of the amorphous content using a region where no crystalline peaks appear in the mixture pattern (130). Since the diffraction in such regions is caused by short-range ordering of amorphous materials, it can be used to estimate the amorphous content present in the sample. The method may be more robust and sensitive than peak intensity measurements (110) though it is limited to mixtures where crystalline peaks are not present in the entire range of amorphous diffraction.

Other methods for the determination of per cent crystallinity have been reported in literature, for example, using specialized instrument optics (131). If both amorphous and crystalline reference patterns are available, full pattern quantitative or semi-quantitative methods used in crystalline mixture analysis can be applied here as well. Such an example is shown in Fig. 17. Physical mixtures of amorphous and crystalline sucrose were prepared with known weight ratios (0%, 20%, 40%, 60%, 80%, and 100% crystalline). The pure amorphous and pure crystalline patterns were then linearly fitted using Brent minimization (101) to each mixture. A single weight was used per reference pattern (applied to all intensity points) and the sum of squared differences at each intensity point was used as the error metric. All patterns were first

***FIGURE 17*** *XRPD quantitative analysis of physical mixtures of amorphous and crystalline sucrose. Top-to-bottom, amorphous sucrose, 20, 40, 60, 80 and 100% crystalline sucrose.*

normalized to same total diffracted intensity. The calculated per cent crystallinity values for the 20/40/60/80 mixtures were 17.2%, 40.7%, 64.4%, 84.3%, respectively. In practice, this approach coupled with good XRPD data consistently yields results within 5% of actual values for mixtures ranging from 10 to 90% crystalline.

*4.1.5.3 Re-Crystallization of Amorphous Materials* XRPD can also be used to monitor re-crystallization of amorphous materials. A typical application of this kind would be to characterize the extent of crystallinity during processing steps (e.g., scale-up of bulk material, formulation, manufacturing) or simply upon storage over the intended shelf life of the drug product, to ensure safety and efficacy (132). As noted earlier, amorphous materials will have different performance than crystalline counterparts (65,133), including for example sensitivity to moisture (134–136), reduced chemical stability (113,126,137), postcompression hardness (112), and enhanced dissolution rate (81,138).

Figure 18 shows the monitoring of recrystallization of amorphous felodipine by XRPD over a 7 day period. The top pattern is pure amorphous felodipine, the remaining patterns were collected on the same sample stored under ambient conditions (25°C and 50% RH) after a period of 2, 3, 5, and 7 days, respectively. The aforementioned computational methods were used to determine per cent crystallinity in each pattern, with the first and last patterns used as reference amorphous and crystalline material, respectively. Given those assumptions, the pattern collected after

***FIGURE 18*** *Recrystallization of amorphous felodipine monitored by XRPD. Top-to-bottom, amorphous felodipine, same sample after 2, 3, 5, and 7 days in ambient conditions, respectivelly.*

2 days is approximately 5% crystalline, followed by 11% after 3 days and 45% after 5 days. After 7 days the sample is almost completely crystalline.

***4.1.6 Regulatory Considerations*** The Food and Drug Administration's (FDA) New Drug Application (NDA) guideline (139) states that "appropriate" analytical procedures should be used to detect polymorphic, solvated (including hydrated), or amorphous forms of a drug substance. Likewise, the guideline states that it is the applicant's responsibility to control the crystal form of the drug substance. If bioavailabilty is affected by the change in crystal form, the applicant must demonstrate the suitability of the control methods. This highlights the importance of controlling the crystal form of the drug substance and, as shown in previous sections, the use of XRPD can provide essential structural information on crystalline and amorphous forms of a drug substance.

The ICH Q6A document (139) provides clear guidelines on how X-ray information should be used in the NDA. As noted in the section on API characterization, XRPD is one of two broadly accepted methods of providing unequivocal proof of polymorphism by the regulatory authorities (20), the other being single crystal X-ray diffraction. Characterization of the API by X-ray and/or some other method is required by the NDA guidelines as different solid forms may have different properties (20,140). An often-cited example is ritonavir (141), whose amorphous form is up to 20 times more bioavailable than the crystalline form, and which crystallized into a new less soluble form after 2 years on the market. XRPD is directly mentioned in the ICH decision trees as part of the drug application process, Fig. 19 (140,142). Some NDA submissions include XRPD methods on the drug substance.

It is often necessary to establish a specification or test (e.g., XRPD or IR) to ensure that the proper drug form is manufactured. Failure to do so may result in the manufacture of different polymorphs with different properties, potentially altering the dosage form performance (as in the case of ritonavir). Regulatory authorities are aware of such challenges and expect the manufacturer to demonstrate control over the

***FIGURE 19*** *ICH Q6A decision tree directing characterization of the forms by X-ray powder diffraction (adapted by author from Reference (140)).*

crystalline or amorphous form in the manufacturing process. Production scale-up requires a process be developed that can reproducibly make the desired polymorph. Where mixtures of forms cannot be avoided, quantitative control (e.g., using XRPD as outlined earlier) is typically required to ensure that the ratios between forms are maintained. Furthermore, this requirement may extend beyond the manufacturing process and through the retest date of the drug substance and potentially throughout the shelf life of the product, which can be a difficult requirement if the forms interconvert. Quantitative XRPD techniques are typically validated by following the ICH Q2A and Q2B guidance (139). It is therefore advantageous to select the most stable solid polymorph for production, determined using a process called polymorph screening in which XRPD plays a major role as outlined earlier. (The use of the most stable form would ensure that there would be no conversion into other forms).

Certain USP monographs require the use of XRPD on the drug substance. One example is the carbamazepine monograph which states that the X-ray diffraction pattern conforms to that of USP carbamazepine RS, similarly determined (140). The exact method of certification used by the USP in the reference standard is not known. In addition, USP recommends the precision to use when comparing peak positions between different XRPD patterns, that is, a peak in one XRPD pattern that falls within the USP-specified range of a peak in the other pattern is to be considered the same. That precision has varied from 0.1 to 0.2 $^{\circ}2\theta$, depending on the year of USP issue (24).

XRPD has been identified as a unique tool for drug substance and/or product analysis that can directly contribute to FDA's "quality by design" initiative. In addition, this tool can help improve the time to market by providing information regarding the structure of the molecule early on in the development process. Finally, XRPD methods can be used to ensure the drug product and/or substance is consistent and has the same identity, purity, and potency (140).

## 4.2 API Identification

***4.2.1 Analysis of a Drug Product*** XRD is frequently applied to the analysis of a drug product. A simple XRD method used for this purpose might involve the following steps (140):

1. Determination of the XRD patterns of all solid components in the drug product.
2. Selection of a region or regions in $2\theta$ where only the polymorph of interest (analyte) diffracts.
3. Preparation of reference physical mixtures containing all API forms as well as excipients.
4. Development of computational/mathematical methods.
5. Validation of the method following the ICH Q2A and Q2B methods.
6. Application of the method.

Chemometric (PLS) methods (143–146) may also be used to increase sensitivity and lower the detection limit. Such analytical XRD methods can have a variety of

applications ranging from online process monitoring to support in litigation of drug product counter-fitting.

One example of the above approach that also includes quantitative analysis of the active ingredient is the XRD method developed by Suryanarayanan (147). The method was applied to intact tablets and required preparation of mixtures containing various weight fractions of the drug and excipient. The quantitative analysis relied on identifying integrated intensities of several diffraction lines for each compound and calculating their ratios as a function of the weight loading of the drug in the tablet. The reported error for the method was less than 10% for a drug loading of 40% weight-in-tablet.

***4.2.2 Monitoring Effects of Processing and Manufacturing on the API*** XRD has been used to study the effects of processing and manufacturing on the solid form of an API. Many of the previously mentioned XRPD methods used for API characterization can also be applied for this purpose.

For example, the antiviral drug MCC-478, known to exist in several anhydrous polymorphic forms as well as a hydrate, was studied in tablet formulation using XRD (148). The XRD patterns of the tablets containing the various forms of the MCC-478 revealed at least one peak unique to each form—generally a prerequisite for this type of work. A semi-quantitative method was developed to characterize the physical form of the API in intact film-coated tablets despite the relatively low weight loading of the API (<20%) in the tablet that also contained a highly crystalline excipient, mannitol, in much greater proportion (60%). The use of this method confirmed that the aqueous film-coating process did not change the form of the API. Furthermore, the same method was used to verify that the API form remained stable (unchanged) over 6 months under accelerated aging conditions (40°C/75% RH). Therefore, the XRD method found application not only for process control during manufacturing, but also for the quality control of the final product.

With increased emphasis by regulatory authorities on understanding and controlling production processes, the implementation of online XRD methods as part of Process Analytical Technology (PAT) is gaining momentum (140). Production processes that are well understood and controlled are considered to be lower risk than those that have not been subject to PAT. It should be noted that spectroscopic methods (NIR, IR, Raman) are also frequently used to monitor polymorphic conversion during processing. Each method has its advantages and disadvantages but typically XRD methods are capable of analyzing the largest sample volume simultaneously and have been used extensively for this purpose in the cement, gypsum and catalyst industries.

An example application of XRD online monitoring was a study of polymorphic conversion during wet granulation (140,149). Wet granulation is a size enlargement process that uses a binder and water to form larger agglomerates, potentially causing phase transformations during the water addition step. Two enantiotropically related forms of flufenamic acid were monitored with a transition temperature of 42°C. XRD was able to identify the form present at various steps of the process.

Online XRD methods used to monitor crystallization of a drug substance have been the subject of extensive research (e.g., Reference (150)). Online processing cells have

been developed for the examination of temperature-dependant polymorphic changes in pharmaceutical materials using *in situ* XRD. Such cells can recirculate the crystallizing solution and monitor the changes by XRD.

***4.2.3 Intellectual Property Considerations*** XRPD is frequently used to identify and/or characterize new materials in patent application filings. Typically, a list of XRPD peak positions is provided, listing $2\theta$ and/or $d$-space position and relative (to maximum) intensity of crystalline peaks. Estimated experimental errors in position ($2\theta$ and/or $d$-space) may be provided, often adopted from the USP (24). It is important to remember that aforementioned instrumental and sample artifacts can and do affect peak positions and intensities. Therefore, providing strict limits on peak positions or relying on intensity information in patent claims yields data that are too narrowly defined. A skilled patent practitioner should therefore be consulted on how best to incorporate solid-state data into a patent application.

The XRPD peak listings may include a list of all observed peaks that can be visually identified above the noise level in the pattern (typically determined through an intensity threshold). However, since it is unlikely that all such peaks will be reproduced in every XRPD pattern of the material, a subset of low angle, non-overlapping peaks with strong intensity (10% or more of maximum observed peak intensity) may be included as peaks "representative" of the material. In this case, it is helpful to have access to XRPD data collected on more than one type of diffractometer geometry in order to assess the reproducibility of peak intensities, which can frequently be affected by for example, preferred orientation and poor particle statistics in a sample.

Where materials exhibit polymorphism and multiple forms are found, it is typical to provide a listing of characteristic (unique) peaks that differentiate one form of a material from all the other known forms of the same material. For different salts or co-crystals where the material can be differentiated chemically, this consideration may be less important but it still applies to polymorphs of a given salt/cocrystal.

# *Water Determination By Karl Fischer Titration*

**Michael Margreth, Regina Schlink, and Alfred Steinbach**
*Metrohm International Headquarters, Switzerland*

## 1 INTRODUCTION

Besides pH measurement, weighing and acid–base titration, the determination of the water content is one of the most frequently used methods in laboratories around the world. In addition to methods requiring complex apparatus, such as infrared reflection spectrometry, gas chromatography or microwave spectroscopy, two methods in particular have been able to establish themselves:

### 1.1 Drying Methods (Drying Ovens, Infrared Lamps, and Infrared Balances)

This method is commonly found in various standards, but suffers from the following disadvantages:

- In principle the loss on drying (LOD) is determined, and not necessarily the water content. Apart from water, other volatile components of the sample and/or decomposition products are also determined. In order to obtain comparable results, work must be carried out under strictly controlled conditions (temperature and duration of the drying process).

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

- It takes a long time to obtain the analytical results (several hours in a drying oven). This can lead to bottlenecks, for example, in the monitoring of manufacturing processes.

### 1.2 Titration Methods

In contrast to drying, this is a specific and selective method. If no side reactions occur, only water will be determined. The method is rapid (determination normally takes only a few minutes), it can be validated and therefore fully documented. Since its introduction more than 60 years ago (1), it has become indispensable in many laboratories. The name **Karl Fischer** (1901–1958), **KF** for short, is therefore well known in most laboratories.

KF titration allows to determine both free and bound water, e.g., surface water on crystals or the water contained inside them. The method works over a wide concentration range from ppm up to 100% and supplies reproducible and correct results.

## 2 REAGENTS

When developing his new analytical method, Karl Fischer took into account the well-known Bunsen reaction, which is used for the determination of sulfur dioxide in aqueous solutions:

$$SO_2 + I_2 + 2H_2O \rightarrow H_2SO_4 + 2HI$$

This reaction can also be used for the determination of water if sulfur dioxide is present in excess and the acids so produced are neutralized by a base. The selection of pyridine, the base used by Karl Fischer, was actually due to chance: "pyridine was just standing in the shelf". This led to the formulation of the classical KF reagent (KFR), a solution of iodine and sulfur dioxide in a mixture of pyridine and methanol.

### 2.1 Original Formulation According to Karl Fischer

Dissolve 254 g iodine in 5 L of anhydrous methanol. Add 790 g pyridine, mix thoroughly and then add 192 g liquid $SO_2$.

1 mL KFR corresponds to approximately 3 mg $H_2O$.

The titer of this combined reagent was not very stable—titer determinations had to be carried out virtually every day. Help was provided by the use of two-component reagents. The titration solution consisted of 30 g iodine in 1 L methanol. For the reaction solution 60 g $SO_2$ was introduced into a mixture of 300 mL each of methanol and pyridine. The titer of the titration solution prepared in this way (approximately 1.7 mg $H_2O$/mL) only decreased by approximately 1.3% over a 2-month period and could be regarded as being relatively stable.

However, for most applications it is advisable to work with a one-component reagent with a relatively stable titer. In order to obtain such a reagent, the methanol was replaced by ethylene glycol monomethyl ether (Cellosolve).

### 2.2 Further Developments

The noxious odor and toxicity of pyridine was a source of annoyance for many users of the KF method. Work had to be carried out in the fume cupboard, which was helpful to the user but not to the environment. Research was carried out into the use of other bases in order to obtain pyridine-free reagents. During this work it was also found that the KF reaction only proceeded rapidly and stoichiometrically at a pH between 5 and 7.

Among the bases tested with varying success were diethanolamine, sodium acetate, and sodium salicylate. The ideal substance was finally found: imidazole ($C_3H_4N_2$), which is similar to pyridine but odorless and has a higher basicity (2).

The latest trend is to replace the toxic methanol by ethanol. Today there is general differentiation between one-component and two-component reagents; the two compounds are called titrant and solvent in volumetry while in coulometry one has the anode and cathode solutions.

A wide range of KF reagents and auxiliary solutions are offered by various manufacturers. They are intended for particular applications, that is, custom-made:

- One-component and two-component reagents for volumetry and coulometry.
- Pyridine-containing and pyridine-free reagents.
- Special reagents for water determination in aldehydes and ketones.
- Stable volumetric KF reagents with a titer of 1 or 2 mg $H_2O$/mL for the determination of low water contents.
- Solvent additives for fats and oils, with halogenated hydrocarbons (usually undesirable) or without these (e.g., with decanol).
- Solvent additives for polar substances (e.g., salts, sugars).
- Buffer substances or buffer solutions for strongly alkaline or strongly acidic samples.
- Certified water standards from 0.1 to 10 mg/mL $H_2O$ with a density of 1 g/mL.

This wide range of possibilities allows the user to determine the water content in practically any matrix (3). It is certainly no longer worth preparing the reagents yourself!

## 3 CHEMICAL REACTIONS

Karl Fischer presented the following equation for water determination with his reagent:

$$\begin{aligned} &2H_2O + SO_2 \times (C_5H_5N)_2 + I_2 + 2C_5H_5N \\ &\quad \rightarrow (C_5H_5N)_2 \times H_2SO_4 + 2C_5H_5N \times HI \end{aligned}$$

This would result in molar ratios of

$$H_2O : I_2 : SO_2 : \text{pyridine} = 2 : 1 : 1 : 4$$

under the assumption that methanol only functions as a solvent and pyridine forms additive compounds with the acids.

However, this molar ratio was incorrect, as established by the studies of Smith, Bryant, and Mitchell (4). These authors recognized the participation of methanol and determined the following molar ratios:

$$H_2O : I_2 : SO_2 : \text{pyridine} : CH_3OH = 1 : 1 : 1 : 3 : 1$$

In a first partial reaction water forms the (hypothetical) pyridine sulfur trioxide, which then further reacts with methanol:

$$H_2O + I_2 + SO_2 + 3C_5H_5N \rightarrow 2C_5H_5N \times HI + C_5H_5N \times SO_3$$

$$C_5H_5N \times SO_3 + CH_3OH \rightarrow C_5H_5N \times HSO_4CH_3$$

The authors subsequently revised this equation by formulating iodine and $SO_2$ as pyridine adducts.

Based on the pH dependency of the reaction constants Verhoef and Barendrecht (5) later realized that it is not the $SO_2$ in the KF reagent that forms the reactive component, but rather the monomethyl sulfite ion that is formed from $SO_2$ and methanol:

$$2CH_3OH + SO_2 \rightleftarrows CH_3OH_2^+ + SO_3CH_3^-$$

They also established that pyridine does not take part in the reaction but only acts as a buffer substance (such that at the same pH the same reaction rate is achieved with sodium salicylate). Pyridine can therefore be replaced by another suitable base (RN). The added base results in a considerable displacement of the equilibrium to the right:

$$CH_3OH + SO_2 + RN \Rightarrow [RNH]SO_3CH_3$$

This means that the KF reaction in methanolic solution can now be formulated as follows:

$$H_2O + I_2 + [RNH]^+SO_3CH_3^- + 2RN \rightarrow [RNH]^+SO_4CH_3^- + 2[RNH]^+I^-$$

### 3.1 Influence of the Water Content

The water content of the working medium influences the stoichiometry of the KF reaction. If it exceeds 1 mol/L (18 g/L) then the reaction behavior changes in favor of the Bunsen reaction for aqueous solutions. This means that two $H_2O$ are

consumed for one $I_2$ or one $SO_2$. It is uneconomic to titrate such a high water content in a large volume of sample. In this case it is important to dilute the sample and/or to use a small amount of sample. If two-component KF reagents are used then the water capacity of the solvent must be taken into consideration, particularly for subsequent titrations. The water capacity of these solvents is normally about 5–7 mg/mL, for a solvent volume of 25 mL this means maximum 125–175 mg $H_2O$.

### 3.2 Influence of the Organic Solvent

Theoretically non-alcoholic KF reagents can also be used, but in this case the stoichiometry also changes. In protic solvents, for example, methanol or ethanol, the ratio is $H_2O{:}I_2 = 1{:}1$, in aprotic solvents, for example, DMF, the ratio is $H_2O{:}I_2 = 2{:}1$. Intermediate values (uneven ratios) have been observed, for example, with propanol, butanol, and other long-chain alcohols. This has to do with the reactivity of the alcohol used. In methanol about 100%, in propanol approximately 80% and in butanol only approximately 50% is present as sulfite ester. With the KF reagents normally used an alteration in the stoichiometry is not to be expected because:

- the titer determination and water determination are carried out in the same titration medium and
- the alcohol fraction in the sample solution continuously increases during the course of the titration.

### 3.3 Kinetics of the KF Reaction

Cedergren [6,7] was presumably the first to thoroughly investigate the KF reaction sequence and establish that the reaction rate increases as the concentrations of $SO_2$, $I_2$, and $H_2O$ increase. The reaction is first order referring to each individual component. For the rate constant K he used the equation:

$$-\mathrm{d}[\mathrm{I_2}]/\mathrm{dt} = \mathrm{K}[\mathrm{I_2}] \times [\mathrm{SO_2}] \times [\mathrm{H_2O}]$$

to obtain the value:

$$K = (1.2 \pm 0.2) \times 10^3\ \mathrm{L^2/mol^2/s} \qquad \log K = 3.08 \pm 0.08$$

Verhoef and Barendrecht confirmed the results of Cedergren, but at the same time found that the reaction constant $K$ depends on the pH of the solution:

- Up to pH = 5, log $K$ increases linearly with the pH.
- Between pH = 5.5 and 8 the reaction rate is constant (there is a plateau).
- Above pH 8, the reaction rate again increases slightly (probably due to side reactions).

From the increases in $K$ under acidic conditions the authors concluded that not $SO_2$, but the sulfite base is the reactive component.

The reaction rate is also strongly influenced by the concentration of iodide ions. The iodine in the KF solution reacts with iodide to form triiodide; this strongly displaces the equilibrium to the right:

$$I_2 + I^- \Rightarrow I_3^-$$

However, during the oxidation of the methyl sulfite the free iodine reacts far more quickly than the triiodide ($\Delta K$ approximately $10^4$). This reaction is also pH-dependent.

## 4 VOLUMETRY AND COULOMETRY

The following are important for both methods (8):

- the KF reagent must be added accurately, reproducibly, and with the highest possible resolution and
- the titration cell must be as impervious as possible. It should be penetrated by as little atmospheric water as possible;
- the water adhering to the walls of the titration cell (inner water film) must be removed by swirling about the conditioned contents of the titration vessel.

### 4.1 Volumetry

It is only since the introduction of piston burets by Metrohm in the 1950s that it has been possible to carry out volumetric Karl Fischer titrations without requiring a cumbersome setup. The introduction of the Exchange Units (also by Metrohm) in the 1960s brought further improvements.

By way of example, Metrohm Titrinos titrate with a resolution of 10 000 pulses per buret volume, while Metrohm Titrandos have a resolution of 20 000 pulses per buret volume. Normally piston burets with a volume of 5, 10, or 20 mL are used for the titration; this means that the Titrinos have a resolution of 0.5–2 μL and the Titrandos' resolution is even 0.25–1 μL.

Although this resolution allows a high precision, this does not mean that titrations can be carried out down to the resolution limit. Even with impervious titration cells the introduction rate of atmospheric humidity can amount to a reagent consumption of 20 μL per min. Modern titrators determine this value as the blank drift and automatically include it in the final calculation.

Higher (absolute) water contents are preferably determined by volumetric titration. Volumetry also has the advantages that solid or pasty samples can be introduced directly into the titration vessel and work can be carried out with a variety of suitable organic solvents specially adapted to particular sample.

Of course it is also possible to determine small amounts of water volumetrically, for example, in solvents. If an appropriate amount of sample and diluted KF reagents are used then the lower determination limit is approximately 50–100 ppm $H_2O$.

Despite great progress in the manufacture of KF reagents, these do not have a stable titer. One of the minor disadvantages of volumetry is therefore that the titer has to be determined at regular intervals.

## 4.2 Coulometry

Instead of a buret the electric current is used for generating a reagent—an "electronic buret", so to speak. The current releases the stoichiometrically corresponding amount of iodine from the iodide-containing KF reagent by electrolysis.

Faraday's law applies: $m = \frac{M \times Q}{z \times F}$

where m is the mass of converted substance in g, M is the molar mass in g/mol, Q is the measured amount of charge in ampere-seconds, z is the number of exchanged electrons (equivalence number, charge number), $F$ is the electrochemical equivalent (1 F = 96.485 coulomb/mol, 1 coulomb = 1 C = 1 ampere-second = 1 A s).

Example for iodine: $2I^- - 2e^- \rightarrow I_2$

$$z = 2,\ M = 253.8(I_2)$$

126.9 g iodine is released by 96,485 A in 1 s—or 1.315 mg iodine is generated by 100 mA in 10 s.

Requirements for coulometric titration are

- The process must take place with 100% current efficiency, that is, there must be no side reactions.
- Oxidation or reduction must lead to a defined oxidation stage.

Current KF Coulometers meet these requirements with modern coulometric reagents. They work according to the galvanostatic coulometry principle, that is, with a constant current.

The same chemical processes take place as in a volumetric KF titration, that is, $H_2O$ consumes one $I_2$. As the iodine is generated electrolytically from the iodide in the KF solution this means that the coulometric determination of water is an absolute method—a titer does not need to be determined!

In order to generate iodine at the anode, Metrohm KF Coulometers work with variable current strengths and pulse lengths (100, 200, and 400 mA—with diaphragm-less cells with a constant current strength of 400 mA). Higher current strengths have not been able to establish themselves—side reactions occur and heat is produced. Working with variable pulse lengths allows precise "iodine addition" even in the region of the titration endpoint.

The instrument measures the time and current flow that is required to reach the titration endpoint. The product of "time × current" is directly proportional to the amount of iodine generated and therefore to the amount of water determined.

Coulometric water determination is primarily used for the determination of small amounts of water. Larger amounts of water require a lot of time and/or may exceed the water capacity of the KF reagent, which could lead to incorrect results. Modern

KF Coulometers typically have a determination range of 10 μg–200 mg $H_2O$ with a resolution of 0.1 μg $H_2O$.

## 5 DETECTION METHODS

In order to determine the end of the KF reaction—that is, the titration endpoint at which all the $H_2O$ has been converted—a detection or indication method is required. Titrimetric volumetric analysis stands and falls with correct endpoint recognition. This means that the indication method is crucial as it determines to a great extent the reproducibility and, above all, the correctness of the results.

### 5.1 Visual or Photometric Indication

Karl Fischer himself only had the possibility of determining the titration endpoint visually. This method requires a high degree of routine and can normally only be used for uncolored sample solutions. When excess iodine is present the solution turns increasingly yellow to brown (the latter with a large excess of iodine). This already indicates the difficulty of deciding the coloration point to which the titration is to be continued. In addition, the coloration in polar solvents (e.g., methanol) differs from that in nonpolar solvents (e.g., chloroform, DMF). Further disadvantages of these methods are that they can hardly be automated or validated. They fell out of use rapidly as electrometric indication methods became available toward the end of the 1940s.

### 5.2 Electrometric Indication Methods

In the meantime indication methods using two polarized electrodes have established themselves. Double Pt-wire or double Pt-ring electrodes are commonly used.

***5.2.1 Biamperometric Indication ($U_{pol}$ or Dead Stop)*** In this case a constant voltage of max. 500 mV is applied to the electrodes and the resulting current is measured. This method was first used mainly for aqueous iodometric titrations. The following reactions occur at the electrodes:

$$\text{Cathode}: \quad I_2 + 2e^- \rightarrow 2I^- (\text{reduction})$$

$$\text{Anode}: \quad 2I^- - 2e^- \rightarrow I_2 (\text{oxidation})$$

The relationship between the voltage, current, and concentration of the depolarizer (iodine or triiodide) is similar to that found in polarography, that is, initially only low voltages are required to produce a flow of current. Then the voltage increases steeply—as a function of the iodine concentration—and, when the limiting diffusion current has been achieved, the current increases only slightly. If the voltage is then further increased decomposition of either the solvent or conductive salt could occur.

***FIGURE 1*** *Biamperometrically indicated titration curve.*

This means that a current flows for as long as iodine is present. When the iodine has been consumed (e.g., by titration with thiosulfate) the current drops abruptly to 0 (which is where the name "dead stop" comes from), the resistance between the electrodes increases strongly and the electrodes are again polarized. In KF titration the reverse occurs. If excess $H_2O$ is present only a minimal current flows; this increases to a few μA when excess iodine is present. The "water loss" resulting from electrochemical conversion can be ignored. At 50 μA for 30 s it is theoretically approximately 1 μg $H_2O$. Figure 1 shows an example of a biamperometrically indicated titration curve:

***5.2.2 Bivoltametric Indication ($I_{pol}$)*** In this case, a small direct or alternating current is applied between the electrodes and the resulting voltage is measured. AC is much more sensitive than DC, which is why AC is usually only used for coulometric titrations. The shape of the titration curve is similar to that obtained by biamperometry; however, the jumps are usually more marked and larger. If the sample solution and titrant are electrochemically active then peak-shaped or V-shaped titration curves (Fig. 2a) are obtained. If only one partner is electrochemically active (the KFR with excess iodine) then L-shaped curves are obtained (Fig. 2b).

The resulting voltages for excess iodine or water depend, of course, on the applied current ($I_{pol}$). Three examples (double Pt-wire electrode):

$I_{pol} = 50$ μA, $U$ approximately 100 mV for excess iodine, approximately 680 mV for excess $H_2O$;
$I_{pol} = 10$ μA, $U$ approximately 5 mV for excess iodine, approximately 580 mV for excess $H_2O$;
$I_{pol} = 1$ μA, $U$ approximately 0 mV for excess iodine, approximately 350 mV for excess $H_2O$.

The titration endpoint is determined by entering a switch-off voltage; reagent addition ceases when this limit is undercut. This "ideal endpoint" is best found

***FIGURE 2*** *Examples of bivoltametrically indicated titration curves.*

experimentally. If a too low voltage is selected then the amount of excess iodine required to achieve the switch-off point will be too large. If it is too high then the titration will not start because no free iodine is required for this voltage to be achieved (decomposition of the solvent or electrolyte).

Once all the water has reacted, the indicator electrode detects the very slight excess of iodine and the Karl Fischer titration stops. In comparison to the visual methods, the electrometric methods have the advantage that the titration is always carried out to the same slight excess of iodine and in this way a better reproducibility and accuracy can be achieved.

## 6 INSTRUMENTS

### 6.1 Volumetric Karl Fischer Titration

Different manufactures offer instruments for volumetric KF titration, ranging from simple instruments for routine determinations up to high end equipment with

***FIGURE 3*** *901 Titrando with 900 Touch Control and 803 KF Titration Stand (Metrohm AG).*

numerous advantages. What all instruments have in common is that they are easy to operate and produce rapid, accurate, and reproducible results.

The Karl Fischer titrators, one example is shown in Fig. 3, are automated titration systems that carry out the titration automatically, that is, the titration rate and volume increments are controlled according to the signal measured by the indication system. In addition, the sample weight can be transmitted directly to the titration system via a connected balance. Results, curves, parameters, and the configuration data can either be printed out or transferred to a PC database.

The titrators have both bivoltametric ($I_{pol}$) and biamperometric ($U_{pol}$) endpoint detection. For both types of detection, the control parameters can be freely selected. This has the advantage that the control parameters can be optimized for difficult samples and special reagents, for example, for the addition of solubility promoters. Good results are normally obtained with the default settings.

Slowly reacting reagents (e.g., those containing pyridine) require an additional stop delay when the endpoint is reached, that is, the endpoint voltage or the endpoint current must be maintained for a few seconds when the endpoint has been reached. In the course of the development of new reagents and the improvement of the instruments, this stop delay has been replaced by the drift-stop criterion. In addition to a pre-defined voltage (or current), a certain drift value must also be achieved. The drift is the amount of consumed KF reagent per unit time to keep the titration cell dry. In general, the drift value for titration cells titrated to dryness is in the order of a few μL/min. The aim of the absolute drift-stop correction is to achieve the drift value measured before the titration. In practice it has been shown that the

achievement of an identical drift can considerably increase the titration time, which is why the use of a relative drift-stop criterion is recommended. If a relative drift stop is used then the titration will be stopped at a slightly higher drift than the initial drift.

If very small amounts of water are to be determined, or if a long titration time is necessary, then work should be carried out using automatic drift correction. In this case the drift value is multiplied with the titration time and the value obtained is subtracted from the added volume.

In addition to the indication system, the resolution of the buret makes a contribution to the accuracy and reproducibility of the results. Metrohm standard burets, for example, add the reagent with a resolution of 10,000 steps per cylinder volume. For a 5 mL buret, this means that in the region of the endpoint, addition will be carried out in 0.5 μL steps. If a Titrando is used in combination with an intelligent Exchange Unit, you can store not only the current titer on the data chip of the Exchange Unit but also carry out reagent addition with the unique resolution of 20,000 steps per cylinder volume.

In principle all commonly available KF reagents can be used with the current KF titrators. Since these reagents do not have a stable titer, it must be determined regularly. The interval between the titer determinations depends on the choice of reagent as well as on how impervious the reagent bottle is.

Leading reagent manufacturers offer certified water standards for determining the titer. It is also possible to determine the titer with ultrapure water. In this case work has to be carried out with very small volumes and handling takes some getting used to. This is why the use of certified standards is recommended; it is possible to back-weigh the added amount and volume dosing is no longer necessary. Solid substances such as di-sodium tartrate dihydrate can also be used, but care must always be taken that the substance is completely dissolved. Standard solutions are available with water contents of $10.0 \pm 0.1$ mg/g (for volumetric water determination), $1.0 \pm 0.03$ mg/g, or $0.1 \pm 0.005$ mg/g (for coulometric determinations) and are offered in ampoules. When handling the standards proceed as follows:

Immediately after the ampoule is opened a syringe is approximately half-filled with the standard solution. The syringe is rinsed by inverting it and ejecting the complete contents (air and standard solution). This is to ensure that the inner walls of the syringe are completely wetted with the solution. The syringe is then filled with the whole of the remaining ampoule contents without entraining any air. After the needle has been wiped off the syringe is tared on a balance and the KF titrator is started. Part of the standard solution is then injected at one go. There are two ways of doing this:

- The standard solution is injected directly beneath the surface of the KF solution.
- It is injected without immersing the needle. The last drop is drawn back into the syringe.

The syringe is then pulled out and back-weighed. The sample weight can be transmitted directly from the balance to the KF titrator or entered manually.

Particular attention should also be given to the titration cell. Water is present everywhere: at a relative humidity of 60%, 0.5 mL air at 25°C contains approximately 7 μg $H_2O$. This is why it is essential that the titration cell is impervious; it should be checked at regular intervals. Special attention should be paid to the sealing rings of the titration cell and the molecular sieve—check the drift! The titrator automatically conditions the titration cell before and between determinations. It is advisable to swirl the cell about from time to time in order to remove any water adhering to the walls. It is important that a constant drift value that is as low as possible is achieved.

## 6.2 Coulometry

In contrast to volumetric Karl Fischer titration, in KF coulometry no titrant is added but the required iodine is generated directly in the iodide-containing electrolyte by electrochemical means ("electronic buret"). There is a strictly quantitative relationship between the amount of electric charge and the amount of iodine generated. This relationship allows the extremely precise addition of the iodine.

KF Coulometers such as the 851 Titrando (Fig. 4) work with variable current strengths and pulse lengths (100, 200, and 400 mA) for generating iodine at the anode.

***FIGURE 4*** *851 Titrando with 900 Touch Control, 801 Stirrer, and 800 Dosino (Metrohm AG).*

PSE415 03/26/2013 8:54:23 Page 14

Higher current strengths have not proven themselves in practice—side reactions can occur and excess heat is produced. Working with variable pulse lengths allows precise "iodine dosification" even in the region of the titration endpoint.

The instrument measures the time and current flow that is required to reach the titration endpoint. The product of time and current is directly proportional to the amount of iodine generated and therefore the amount of water determined.

Coulometric water determination is primarily used for the determination of small amounts of water. Larger amounts of water require a lot of time and/or may exceed the water capacity of the KF reagent, which could lead to incorrect results. Metrohm KF Coulometers, for example, have a determination range of 10 μg–200 mg $H_2O$ with a resolution of 0.1 μg $H_2O$.

The iodine is produced by a generator electrode. There are two different types of generator electrodes:

A. *Generator electrode without diaphragm [9–11]:* The generator electrode without diaphragm (Fig. 5) is easy to handle and easy to clean. Only a single reagent is required. However, care must be taken that only those reagents that are intended for generator electrodes without diaphragm are used. As no moisture can adhere to the diaphragm there is a further advantage—the electrode is rapidly ready for use.
B. *Generator electrode with diaphragm:* A generator electrode with diaphragm (Fig. 5) should be used whenever your samples contain ketones and aldehydes, as the special reagents used for them are only available for generator electrodes with diaphragms. An electrode with diaphragm should also be used for reagents with a low conductivity (the addition of chloroform, for

***FIGURE 5*** *Generator cells for KF Coulometers: on the left without, on the right with diaphragm (Metrohm AG).*

example, reduces the conductivity) and when measurements are to be made in the lower trace range. Reagents for coulometric water determination consist of an anolyte that is filled into the titration vessel and a catholyte that is filled into the cathode compartment. Both liquids should have about the same level in order to prevent pressure differences from forcing the anolyte into the cathode compartment and vice versa.

The endpoint is determined by a double platinum electrode and is largely similar to that in volumetric Karl Fischer titration.

As the coulometric KF method is an absolute method this means that no titer has to be determined. It must only be ensured that the reaction that generates the iodine takes place to 100%. Although this is the case with the reagents that are available, the whole system should be checked from time to time with the aid of certified water standards with a water content of $1.0 \pm 0.03$ mg/g or $0.1 \pm 0.005$ mg/g. Handling the standards is described in 6.1 "Volumetric KF titration".

In coulometry, cells made completely of glass are used as titration cells, as cells with a plastic cover have a certain permeability to water vapor. This does not have much influence on volumetric KF titrations, as these are normally used to determine higher water contents than in KF coulometry. Care must also be taken that the cell is as impervious as possible.

### 6.3 Karl Fischer Oven

Many substances only release their water slowly or at elevated temperatures. This means that they are not suitable for direct Karl Fischer titration. A further problem is the low solubility of certain samples in alcohols. In such cases traditional methods recommend complicated sample preparation procedures or the use of solubility promoters, which represent a health hazard. Other substances react with the KF reagents to release water or consume iodine; this falsifies the results.

These problems can be avoided by using a heating method. The substance under investigation is heated in an oven located upstream from the cell and the released water is transferred by a flow of dry carrier gas to the titration cell where it is determined by Karl Fischer titration. As only the water enters the titration cell and the sample itself does not come into contact with the KF reagent, this means that side reactions and matrix effects are ruled out. Work is carried out either with a conventional tube oven or with an oven using the vial technique:

The 860 KF Thermoprep uses the vial technique. The samples are weighed out directly into vials that are then hermetically sealed and placed in the oven. A double hollow needle pierces the vial septum. A stream of dry carrier gas (air or inert gas) is introduced through the inlet needle and passes through the heated sample. The carrier gas containing the released moisture then passes through the outlet needle and via a heated transfer tube directly into the titration cell, in which the Karl Fischer water determination takes place. Depending on the water content of the sample the determination can be carried out volumetrically or, in the trace range, coulometrically. Working with vials means that the oven cannot be contaminated

by the sample and, as a result, no carryover or memory effects can occur. In addition, the hermetic vial seals with PTFE-coated septa reliably prevent the water content from being falsified by atmospheric moisture.

## 6.4 Automation in Karl Fischer Titration

The use of a sample changer is well worthwhile for large numbers of samples. The advantages are not only the amount of time saved by the laboratory personnel: automated systems control the operating procedures and improve both reproducibility and accuracy. In automated KF titration there is an additional difficulty; normal KF sample changers do not work in closed systems and penetration by atmospheric moisture cannot be prevented. For a water content $>1\%$ this interference can be corrected by the subtraction of a previously determined blank value. In principle, the use of such sample changers can only be recommended for volumetric determinations.

The MATi 10 system in Fig. 6 allows the automation of volumetric Karl Fischer titrations. The samples are weighed out into beakers, sealed to protect them against atmospheric moisture, and placed on the rack. Before titration the samples are

***FIGURE 6*** *The MATi 10 system for the automation of volumetric Karl Fischer titrations (Metrohm AG).*

***FIGURE 7*** *The MATi 4 system for automated coulometric titrations (Metrohm AG).*

dissolved in a known amount of Karl Fischer working medium and the water content is then titrated in a second step. This method is particularly suitable for samples that dissolve quickly in the KF working medium. The solubility can also be improved by the use of a suitable solubility promoter.

It is also possible, however, to automate the analysis of samples with a water content $<1\%$.

The 815 Robotic USB Sample Processor Xl (Fig. 7) is a fully automated system for coulometric titrations with high sample throughput. As in the oven technique, the samples are weighed out into vials, hermetically sealed with septa and placed on the sample rack. With the aid of a pipetting system adapted to the special conditions of the KF titration (minimization of the penetration of atmospheric humidity), a defined volume of the sample is transported to the coulometer cell where the water content is determined.

By using the 874 USB Oven Sample Processor (Figs 8 and 9), automation of the heating method is also possible. The principle corresponds to that of the 860 KF Thermoprep, with the exception that the sample vials are placed on the rack of the 874 USB Oven Sample Processor. During the analysis, the turntable positions the sample vial above the oven. The vial is then lowered automatically into the heating block.

In addition, the 874 USB Oven Sample Processor offers the possibility of using temperature gradients. The recorded water release curve can be used to determine

PSE415 03/26/2013 8:54:26 Page 18

***FIGURE 8*** *874 Oven Sample Processor with 851 Titrando (Metrohm AG).*

***FIGURE 9*** *Side view of the 874 USB Oven Sample Processor (Metrohm AG).*

PSE415 03/26/2013 8:54:28 Page 19

the optimum heating temperature for the particular sample. The curve also allows statements to be made about the kinetics of water release as a function of the temperature. Depending on the water content of the sample, the titration can be carried out volumetrically or, in the trace range, coulometrically.

## 6.5 Accessories for Karl Fischer Titration

A wide range of accessories makes it easier to carry out Karl Fischer titrations in the laboratory.

Use the 803 KF Titration Stand (Fig. 10) for stirring and manual exchange of the used titration solution. Solvents can be added and aspirated with the built-in membrane pump without having to open the cell. This considerably shortens the conditioning time and minimizes reagent handling by the user.

With KF Coulometers or a Titrando, reagent exchange is even easier to carry out by using a Dosino. All you have to do is define the time and the instrument will carry out the exchange automatically.

***FIGURE 10*** *803 KF Titration Stand.*

***FIGURE 11*** *Weighing spoon for solid samples.*

If special additional steps are necessary, such as titration of a heated solution or homogenization of the sample in the titration cell, then special accessories are available to suit your particular application. Some examples are shown in Figs 11 and 12.

## 7 SIDE REACTIONS

KF water determination is only specific if no side reactions with the KF reagents take place. This means that no water should be released in side reactions, nor should the sample consume or release iodine. Most side reactions can be suppressed by suitable measures. The most important interfering substances are as follows.

### 7.1 Carbonates, Hydroxides, and Oxides

During the KF titration, methyl sulfuric acid and hydriodic acid are produced. Although these are attached to the base, they still form weak acids that react with the above-mentioned compounds to form salts and release water:

$$Na_2CO_3 + 2HI \rightarrow 2NaI + CO_2 + H_2O$$

$$Ca(OH)_2 + H_2SO_4 \rightarrow CaSO_4 + 2H_2O$$

$$MgO + 2HI \rightarrow MgI_2 + H_2O$$

***FIGURE 12*** *Heatable cell for titrations at elevated temperatures.*

Not all oxides take part in an acidic reaction. In addition to alkali oxides and alkaline earth oxides, the presence of the following oxides leads to the formation of water: $Ag_2O$, HgO, $MnO_2$, PbO, $PbO_2$, and ZnO.

We recommend to determine the $H_2O$ in these compounds by the oven method.

## 7.2 Aldehydes and Ketones

These two classes of compounds combine with the methanol in the KFR to form acetals and ketals respectively with the release of water.

$$\text{Aldehyde; } RHC = O + 2CH_3OH \rightarrow \text{Acetal; } RHC(OCH_3)_2 + H_2O$$

$$\text{Ketone; } R_2C = O + 2CH_3OH \rightarrow \text{Ketal; } R_2C(OCH_3)_2 + H_2O$$

With aldehydes the reactivity decreases as the chain length increases. Aromatic aldehydes react more slowly than aliphatic aldehydes. Acetaldehyde reacts the quickest and causes the most problems. However, there are always exceptions to any rule, formaldehyde and chloral do not form acetals and can be titrated without any problems.

Ketones are less reactive than aldehydes. The reactivity also decreases as the chain length increases. Ketal formation is most rapid with acetone and cyclohexanone. The following are regarded as being stable (no ketal formation): diisopropyl

ketone, benzophenone, deoxybenzoin, benzil, benzoin, camphor, alizarin, dibenzalacetone, and dichlorotetrafluoroacetone.

Acetal and ketal formation is also influenced by the alcohol present. As the chain length increases the reactivity decreases. This means that methanol is the quickest to react.

There are several ways of preventing acetal or ketal formation:

a. By using KF reagents specially labeled for this purpose.
b. By using methanol-free KF reagents. Methanol is replaced by a higher alcohol, for example, 2-methoxyethanol.
c. By making use of the different reaction rates and slowing down acetal or ketal formation so much that they do not interfere with the titration. This can be achieved by carrying out the titration at $-10°C$. This also freezes hydrogen sulfite addition (see following section).

With aldehydes a second reaction—hydrogen sulfite addition—can also interfere. In this case $H_2O$ is consumed, so that the water content determined could be too low.

$$RHC = O + SO_2 + H_2O + NR' \rightarrow RHC(OH)SO_3HNR'$$

## 7.3 Strong Acids

Strong acids can react with the methanol contained in the KF reagent and release water:

$$2CH_3OH + H_2SO_4 \rightarrow (CH_3O)_2SO_2 + 2H_2O$$

$$CH_3OH + HOOCH \rightarrow CH_3O\text{-}OCH + H_2O$$

Among the organic acids the strongest esterification is shown by formic acid; acetic acid only undergoes partial esterification. Methanol esterifies the quickest. Slower reaction rates are achieved with propanol or 2-methoxyethanol or both.

However, strong acids also lower the pH value of the reaction solution so much that the KF reaction either stops or proceeds unsatisfactorily. The reaction mixture can be buffered by the addition of a base (e.g., imidazole) and the pH value brought back to the optimal range again. If this measure is taken then no esterification occurs even with strong mineral acids (e.g., $H_2SO_4$ or $HNO_3$).

## 7.4 Silanols and Siloxanes

The terminal silanol groups esterify with the methanol contained in the KF reagents and release water. This means that methanol-free reagents must be used to determine the water content of these substances.

$$R_3SiOH + CH_3OH \rightarrow R_3SiOCH_3 + H_2O$$

## 7.5 Boron Compounds

Boric acid reacts with methanol with esterification and the release of water:

$$H_3BO_3 + 3CH_3OH \rightarrow B(OCH_3)_3 + 3H_2O$$

Boron trioxide ($B_2O_3$), metaboric acid ($HBO_2$), and borax/sodium tetraborate ($Na_2B_4O_7$) all react in the same way.

The esterification rate decreases as the chain length of the alcohol increases (methanol esterifies the quickest).

## 7.6 Metal Peroxides

These form water with KF solutions and cannot be titrated directly. In some cases, the oven method can be used (provided that the substances release their $H_2O$ at $<250°C$).

## 7.7 Reducing Agents

Reducing or oxidizing agents can react with the iodine in the KF reagents and simulate a water content that is too high or too low, respectively.

0.5 mol $H_2O$/mol substance in the sample is simulated by:

$$\text{Iron(III) salts} \quad FeCl_3 \times 6H_2O + 5.5I_2 + 6SO_2 + 6CH_3OH \rightarrow FeI_2 + 9HI + 3HCl + 6CH_3SO_4H$$

$$\text{Copper(II) salts} \quad CuCl_2 \times 2H_2O + 1.5I_2 + 2SO_2 + 2CH_3OH \rightarrow CuI + 2HI + 2HCl + 2CH_3SO_4H$$

$$\text{Nitrites} \quad KNO_2 + 0.5I_2 + SO_2 + CH_3OH \rightarrow KI + NO + CH_3SO_4H$$

$$\text{Thiosulfates} \quad 2Na_2S_2O_3 + I_2 \rightarrow 2NaI + Na_2S_4O_6$$

1 mol $H_2O$/mol substance in the sample is simulated by:

$$\text{Ascorbic acid (Vitamin C)} \quad C_6H_8O_6 + I_2 \rightarrow C_6H_6O_6 + 2HI$$

$$\text{Disulfites} \quad Na_2S_2O_5 + I_2 + CH_3OH \rightarrow 2NaI + SO_2 + CH_3SO_4H$$

$$\text{Hydrazine and its derivatives} \quad 2N_2H_4 + 2I_2 \rightarrow N_2H_6I_2 + N_2 + 2HI$$

$$\text{Selenites} \quad Na_2SeO_3 + I_2 + 3SO_2 + 3CH_3OH \rightarrow 2NaI + Se + 3CH_3SO_4H$$

$$\text{Sulfites} \quad Na_2SO_3 + I_2 + CH_3OH \rightarrow 2NaI + CH_3SO_4H$$

$$\text{Tellurites} \quad Na_2TeO_3 + I_2 + 3SO_2 + 3CH_3OH \rightarrow 2NaI + Te + 3CH_3SO_4H$$

$$\text{Tin(II) salts} \quad SnCl_2 \times 2H_2O + 3I_2 + 2SO_2 + 2CH_3OH \rightarrow SnI_4 + 2HI + 2HCl + 2CH_3SO_4H$$

2 mol $H_2O$/mol substance in the sample is simulated by:

Arsenites $NaAsO_2 + 2I_2 + 2SO_2 + 2CH_3OH \rightarrow NaI + AsI_3 + 2CH_3SO_4H$

3 mol $H_2O$/mol substance in the sample is simulated by:

Arsenates $Na_2HAsO_4 + 3I_2 + 4SO_2 + 4CH_3OH \rightarrow 2NaI + AsI_3 + HI + 4CH_3SO_4H$

Mercaptans simulate a higher water content and are oxidized to disulfides:

$$2RSH + I_2 \rightarrow RSSR + 2HI$$

The water content of salts can usually be determined by the oven method. For interfering hydrazines, the following procedure provided good results:

The sample the hydrazine dissolved in methanol and titrated with methanolic iodine solution. This oxidizes the hydrazine and the KF water determination is no longer interfered with. In the same solution, a titration can then be carried out with a combined KF solution. The $H_2O$ content of the methanol used must be determined separately and subtracted from the result.

### 7.8 Oxidizing Agents

These release elemental iodine from the iodides in the KF reaction and simulate a water content that is too low.

a. Dialkyl peroxides, diacyl peroxides, and peresters form iodine. However, the reaction takes place slowly and can be "frozen" at low temperatures. The titration temperature to be used is product-specific and can be as low as −60°C. Hydroperoxides—for example $H_2O_2$—do form iodine, but also an equivalent amount of $H_2O$. The KF titration is free from interference.
b. Elemental chlorine and bromine also release iodine. In this case, excess $SO_2$ is passed through the sample. This reduces these substances to chloride and bromide respectively, which no longer interfere.
c. The water content of dichromates, chromates, and permanganates is determined by the oven method.

## 8 SAMPLE PREPARATION TECHNIQUES

Each sample preparation is preceded by sampling. Particularly with inhomogeneous samples—and there are a lot of them, even if it is not always obvious—this initial step is important for the correctness and accuracy of the results. Correct sampling is therefore an essential requirement for the subsequent determination!

Many standardized methods provide detailed instructions concerning this subject. This may also apply for in-house instructions. If no instructions are available then the following points must be observed:

- The water content of the sample taken must be the same as the average water content of the original sample—that is, the sample must be representative.
- Atmospheric moisture is an ever-present source of contamination, and not only in tropical countries.
- Hygroscopic samples have a large amount of water adhering to their surfaces.
- Samples that easily release water or become weathered have only a small amount of water on their surfaces.
- Liquids can release water if the water is not present in dissolved form but as a dispersion (precipitation or flotation, adherence to vessel walls—for example, ointments, creams, and lotions). The same applies for samples in which the solubility limit for water is undercut on cooling down.
- The more heterogeneous the water distribution in the sample, the larger the sample to be taken.
- Sampling must take place as quickly as possible and the water content of the sample must not change during transport and storage.

## 8.1 General

Many samples can be weighed out and/or injected directly into the titration vessel or titration cell, provided that they are soluble in the solvent used and do not undergo side reactions with the KFR.

In contrast, other samples require one or more preparation steps. The most important sample preparation techniques are described below. Further information can be found under the individual classes of substances.

It is very important that the sample preparation technique used does not introduce any additional water into the sample and that no water losses occur by heating the sample too strongly.

## 8.2 Dilution

For reasons of accuracy (sample size), samples with a high water content (>40%) are diluted with an inert dry solvent before determination. Methanol can normally be used for this purpose. If the sample contains emulsified fats oils or both then a dry mixture of 60% methanol and 40% decanol (or, if permitted, chloroform) should be used. The procedure is as follows:

Approximately 1 g sample is weighed out exactly into a dry Erlenmeyer flask fitted with a septum stopper. This is treated with approximately 20–25 g dry solvent (mixture), the flask is then sealed, and the contents are mixed. Part of the mixture is drawn off in a dry syringe and the syringe and its contents are tared. Some of the mixture is injected into the titration vessel and titrated. The amount of sample injected is determined by back-weighing the syringe. If a dry solvent is used then it is not absolutely necessary to take its blank value into account. Here is an example:

| | |
|---|---|
| Sample weight | 1.575 g |
| Methanol weight | 22.725 g |
| Injected mixture | 1.500 g |
| KFR titer | 4.855 mg $H_2O$/mL |
| KFR consumption | 6.255 mL |
| *Calculation* | |
| Diluted sample | 22.725 g + 1.575 g = 24.300 g (100%) |
| Sample fraction | 1.575 g: 24.3 g = 0.0648 |
| Injected sample | 0.0648 × 1500 mg = 97.22 mg |
| $H_2O$ found | 6.255 mL × 4.855 mg/mL = 30.37 mg |
| $H_2O$ in sample | 30.37 × 100/97.22 = **31.24%** |

The following samples can be treated in this way:

- Ointments
- Cosmetic lotions and emulsions
- Alcohol-containing samples.

## 8.3 Solvent Extraction

This can take place in two different ways—external or during the titration in the titration vessel. It is usually carried out either warm or hot, less frequently at room temperature. If an external extraction is carried out then please remember that all the water can never be extracted, an average water content between the sample and the solvent is obtained. Example: 10 g sample with a water content of 10% is extracted with 50 mL methanol (density approximately 0.8 g/cm$^3$) with a water content of 100 ppm. The $H_2O$ content of the mixture is 1004 mg/50 g, corresponding to 20.08 mg $H_2O$/g or 2.008% $H_2O$.

This also means that the larger the ratio between the sample and dry solvent, the less water will be extracted from the sample. The blank value of the solvent must, of course, be taken into consideration when calculating the water content.

Better values are obtained if the extraction is carried out directly in the titration vessel and the water is titrated immediately. A titration vessel equipped with a heating jacket and a reflux condenser is used and the titration is carried out, for example, at 50°C. Work can be carried out with or without an extraction time (set at the titrator) as required. If an extraction time is used then please note that a sufficiently long-stop delay must be observed for the endpoint.

## 8.4 Homogenization

In liquids water can float, adhere to the inner walls of the sample bottle, or be deposited on the bottom. This occurs particularly when the sample is taken at a high temperature and allowed to cool down to room temperature before the analysis. The water can again be distributed homogeneously by immersing the bottle in an ultrasonic bath.

The separated water can also be dissolved again by the addition of an exactly weighed-out amount of a solubility promoter (e.g., isopropanol), whose water

***FIGURE 13*** *The 841 Titrando with Polytron PT 1300 D high-frequency homogenizer (Metrohm AG).*

content has been accurately determined (blank value). This method is suitable for pastes and viscous liquids.

Solids are usually inhomogeneous and must be thoroughly comminuted and homogenized. The procedure depends on the constitution of the sample:

Coarse particles, hard and tough: Ball mill or analytical mill (closed) with water cooling. This method is especially suitable for pills.

Coarse, fatty: Grating and high-frequency comminution.

Coarse, soft, inhomogeneous: Comminute with a meat grinder or knife, then high-frequency comminution.

Pasty, inhomogeneous: Homogenization with a blender, then possibly high-frequency comminution.

High-frequency comminution: High-frequency comminution can be directly carried out in the sealed titration vessel. Any alteration to the water content caused by atmospheric humidity is eliminated. With the Titrando/Polytron system shown in Fig. 13 tablets are dissolved in the KF reagent in a short time regardless of their coating.

## 8.5 The Karl Fischer Oven Method

A dry stream of gas is passed through the heated sample; in each case the released water is transferred to the titration vessel and immediately titrated. The heating temperature should be set as high as possible—just high enough so that the sample does not decompose and no interfering secondary constituents distill over. The heating temperature and duration must be optimized in preliminary tests. The appropriate blank values must be subtracted.

This method is used for samples that cannot be extracted (or cannot be completely extracted) with a suitable solvent or that undergo side reactions with the KFR, such as some starting materials for pharmaceutical products.

## 9 KARL FISCHER WATER DETERMINATION IN PHARMACEUTICALS

### 9.1 Water Content in Pharmaceuticals

Quality, hardness, compaction, and shelf life of pharmaceuticals depend to a large extent on the content of adsorbed (surface water) or bound water (water of crystallization). Accordingly, straightforward and accurate methods for water determination are required. Several methods exist for the determination of the water content: loss on drying, Fourier Transform Infrared (FTIR), and Raman Spectroscopy as well as dielectric measurements. Among these, Karl-Fischer titration is certainly the method of choice when trace amounts of water have to be accurately determined in a reasonable time. Hence, for many years now KF titration has been stipulated as the standard method for determining the water content of pharmaceuticals. The most important pharmacopoeias are:

- European Pharmacopoeia (Ph. Eur., (12)) and the
- United States Pharmacopeia (USP, (13)).

Both of these contain detailed information about sample size/sample weight, titration method (>95% direct volumetric titration), range of the water content permitted, and reagents to be used. The European Pharmacopoeia describes more than 400 substances for which the water content has been determined by the Karl Fischer method, the USP describes more than 700 substances (14).

### 9.2 Direct Volumetric Titration

With methanol in the titration cell, the water content of the following substances has been determined by direct volumetric titration:

Pyrazolone, cipofloxacin hydrochloride, effortil, folic acid, nicotinic acid, and scopolamine hydrobromide.

And in methanol at 50°C:

Glucose, hyaluronic acid sodium salt, lysine acetylsalicylate, acetylsalicylic acid, calcium folinate, and lactose monohydrate.

The water content of the following substances has been determined in a solvent mixture, in some cases after heating to 50°C:

Mannitol and sorbitol (methanol/formamide 2:1), erythromycin (pyridine), isomalt, glucosylmannitol/glucosylsorbitol (methanol/formamide 1:1, ground-up sample), magnesium aspartate, magnesium lactate, calcium glycerophosphate, caffeine (methanol/formamide 2:1, 50°C), glycerol monostearate, and suppositories (methanol/chloroform 2:1, titrant with a titer of 2 mg $H_2O$/mL), lanolin (methanol/

chloroform 1:1), serine phosphoric acid (methanol/formamide 2:1, 50°C), and herb extracts (methanol/formamide 2:1).

## 9.3 Karl Fischer Oven Method for Pharmaceuticals

With some products or substances side reactions can occur if the titration is carried out directly in methanol (pH alteration of the KF system, oxidation by iodine). Moreover, many substances release their water only slowly or at high temperatures. They are therefore not suitable for direct Karl Fischer titration. An additional problem is the low solubility of certain samples in alcohols. In these cases, traditional methods recommend laborious sample preparation procedures or the use of toxic solvents to promote dissolution. The European Pharmacopoeia recommends the quantification via the LOD in a drying cabinet or desiccator. However, besides the water to be determined, this method also includes all volatile compounds (e.g., impurities, decomposition products) released at higher temperatures.

The KF Oven Method allows to resolve these problems (see section 8.4). Depending on the water content of the sample, KF titration can be performed either volumetrically for higher or coulometrically for lower water contents. Considering the relatively small amount of water in most pharmaceuticals, samples are mainly analyzed coulometrically.

***9.3.1 Procedure*** The calculation of the sample's water content involves also the determination of the humidity in the sample vessel and the moisture adhering to the vessel surface, vial cap, and septum. Three empty but sealed sample vials are "analyzed" under the same conditions as the particular sample. The resulting mean value is stored as a blank value and automatically taken into account in the calculation (15).

Subsequently a three-fold determination for each compound is performed. The accuracy of the KF titrations is checked at regular intervals with a certified KF Oven standard.

***9.3.2 Water Release Curve for Metamizole Sodium*** The optimum oven temperature for driving off the water should ensure complete water extraction in a reasonable time excluding decomposition of the sample. This means that the oven temperature should be chosen as high as possible to ensure short determination times, but still be 20–30°C below the decomposition temperature. The oven temperatures for unknown samples are determined on the basis of the water-release curves that were recorded for all investigated pharmaceuticals in the temperature range of 50–250°C (16).

The determination of the adequate oven temperature is illustrated by metamizole sodium, a pharmaceutical that is not accessible to direct KF titration. The dashed curve in Fig. 14 represents the absolute water released as a function of total time while the continuous curve corresponds to the associated drift as a function of oven temperature.

***FIGURE 14*** *Water-release curve for metamizole sodium in the temperature range 50–250°C.*

The water release curve was recorded using a heating rate of 2°C/min. Both surface moisture and water of crystallization are released within the first 1600 s (50–103°C). Afterwards the drift (continuous curve) drops to its original value of approximately 10 µg/min and remains almost constant for 3800 s, increasing again at 5400 s. At 5400 s (230°C), both curves indicate by their increase that water is released by beginning decomposition. Hence, for the rapid determination of the water content of metamizole sodium, a temperature of approximately 210°C assures a fast water release without decomposition.

***9.3.3 Titration Curve for Morphine Hydrochloride*** Figure 15 shows the absolute amount of water (dashed curve) and the drift (continuous curve) as a function of time. The three drift peaks show that morphine hydrochloride is present in the form of its trihydrate. After 180 s no more water is released. The slight increase of the dashed curve can be attributed to the background drift.

***9.3.4 Comparison Karl Fischer Oven Method/Loss on Drying*** In contrast to the wide range of the recovery rates for the LOD specified by the European Pharmacopoeia (65–117%), the KF oven method provides recovery rates between 96 and 101% (Table 1). Additionally, the water content is determined with an excellent repeatability in less than 12 min.

***9.3.5 Advantages of the Karl Fischer Oven Method*** The Oven Sample Processor:

- enables accurate and precise analysis of pharmaceuticals that formerly were not amenable to KF titration,

PSE415 03/26/2013 8:54:30 Page 31

***FIGURE 15*** *Titration curve for morphine hydrochloride at an oven temperature of 180°C. The absolute amount of water (dashed curve) and the drift (continuous curve) are shown as a function of time.*

- avoids contamination of the titration cell; consequently there are no carryover and memory effects,
- works non-destructively and requires only 15–30 mg of the potentially expensive pharmaceutical,
- allows recording of water release curves providing information about the kinetics of the water release,
- significantly reduces manual sample preparation steps,
- enhances sample throughput (high efficiency),
- analyzes all samples under identical and reproducible conditions, providing results of the highest precision.

## 9.4 Alternative Procedures

For some products, the water content cannot be accurately determined neither in methanol nor by the heating method. For these samples the following procedures are suggested (17):

a. Salves and creams are first diluted with methanol/chloroform. Approximately 1.5 g sample is weighed out into a dry Erlenmeyer flask fitted with a septum stopper. Approximately 50 g methanol/chloroform 1:1 is added together with a magnetic stirrer bar, the flask is sealed and vigorously shaken. It is then placed on the magnetic stirrer for 5 min. 25 mL methanol/chloroform 2:1 is placed in the titration cell and titrated to dryness. Sample solution is removed through the septum stopper with a dry syringe and approximately 1 mL is injected into the titration vessel. The sample weight is obtained by differential

**TABLE 1 Results of the Karl Fischer Water Determination for Selected Pharmaceuticals from the European Pharmacopoeia**

| Substance and Empirical Formula | Water Content: Calcul. (%) | Water Content: Loss on Drying[a] (LOD) (%) | Water Content: KF Oven Method (%) | Water Content: KF Oven Method RSD[b] (%) | Recovery: LOD (%) | Recovery: KF | Melting Point (°C) | Temp. 874 Oven (°C) |
|---|---|---|---|---|---|---|---|---|
| Carbidopa $C_{10}H_{14}N_2O_4 \times H_2O$ | 7.37 | 6.9–7.9 | 7.17 | 0.35 | 93.6–107.2 | 97.3 | 203–205 | 150 |
| Cysteinehydrochloride monohydrate $C_3H_8ClNO_2S \times H_2O$ | 10.25 | 8.0–12.0 | 10.33 | 0.30 | 78.0–117.1 | 100.8 | ≥170[c] | 150 |
| Ethacridine lactate monohydrate $C_{18}H_{21}N_3O_4 \times H_2O$ | 4.98 | 4.5–5.5 | 5.05 | 0.59 | 78.0–117.1 | 101.4 | ≥180[c] | 180 |

[a]Given in the European Pharmacopoeia.
[b]Mean value of three-fold determinations.
[c]Melting with decomposition.

Calculated water contents as well as information about the loss on drying given in the Pharmacopoeia.

weighing of the syringe. A blank value for the solvent mixture is determined in the same way.

b. In lozenges the water is determined in the same way as in salves. Three grams comminuted sample is dissolved in 20 g formamide under gentle heating and approximately 1 g is titrated with the separate KF reagents for aldehydes and ketones.
c. Bismuth subnitrate is treated in the same way (5 g sample in approximately 50 g methanol, 2–3 g of the separated out supernatant solution is titrated).
d. Of the highly viscous pentanol approximately 1 g is diluted with approximately 10 g methanol and approximately 2 g of the mixture is titrated with the separate KF reagents for aldehydes and ketones.
e. For amoxicillin, penicillin G (18), dobutamine hydrochloride monohydrate, arginine aspartate, and norepinephrine hydrochloride, 30 mL methanol and 5 g salicylic acid is placed in the titration cell and titrated to dryness; the sample is then added and its water content is determined.
f. For S-carboxymethyl-L-cysteine 20 mL of a 1:1 mixture of methanol/formamide is placed in the titration vessel with 5 mL KF buffer solution and titrated to dryness. Approximately 1 g sample is added and its water content is determined.
g. With adenosine-5′-triphosphoric acid disodium salt imidazole (approximately 3 g) is added to the methanol in the titration cell in order to stabilize the pH of the KF system.
h. Vitamin C (ascorbic acid) and ascorbates are oxidized by the iodine in the KF reagents and an increased water content is simulated. The following procedure—with two-component reagents—is proposed for these substances:

   25 mL methanol is placed in the titration vessel and the sample is dissolved in it. The vitamin C or ascorbate is then titrated with methanolic iodine solution (the titrant consumption does not need to be noted down). 10 mL working medium ($SO_2$ plus base in methanol) is added and the water content is titrated with the same titrant. The blank value of 25 mL methanol + 10 mL working medium (without sample) is determined and taken into account in the calculation.
i. Lindane contains free chlorine and its water content must also be determined with separate KF reagents:

   25 mL working medium ($SO_2$ and base in methanol) is placed in the titration vessel and approximately 2 g sample is added. The solution is stirred for 5 min and the water content is then determined by titration with iodine solution.

   The blank value for 25 mL working medium (without sample) must then be determined separately and taken into account in the calculation.
j. For N-acetylcysteine 20 mL methanol and 5 mL KF buffer solution and 1 g *N*-methylmaleinimide is placed in the titration vessel and titrated to dryness with KF solution. Approximately 1 g sample is added, the solution is stirred for 5 min and the water content is then titrated.

# Chapter 1

## Abstract

A variety of analytical techniques have been used for water determination. These include drying methods and titration methods. In comparison of drying, titration is rapid and can be validated. This article focuses on water determination by Karl Fischer titration.

## Keywords

drying, karl fischer titration, water, chemical reactions, reaction kinetics.

# CURRENT NEEDS FOR NEW THERAPEUTIC AGENTS AND DISCOVERY STRATEGIES—A SYSTEMS PHARMACOLOGY APPROACH

Sophie C. Desbiens and David H. Farb

*Boston University School of Medicine, Laboratory of Molecular Neurobiology, Department of Pharmacology and Experimental Therapeutics, Boston, Massachusetts*

## 1 INTRODUCTION: A BRIEF HISTORY OF DRUG DISCOVERY

The use of remedies to treat or alleviate symptoms of a medical condition can be traced as far back as ancient Egypt. The Ebers papyrus, dating from 1555 BC, was found to contain 876 concoctions to treat a wide variety of disorders [1]. Early medicinal efforts were also used by the Greeks, most notably Hippocrates, and by several Asian cultures including the Chinese [2]. However, the identification of active ingredients and the development of the interdisciplinary science of pharmacology that bridged organic chemistry, zoology, and pharmacology did not emerge until the late 1800's. These advances were made possible by progress in chemistry, including theories on acids and bases and on the structure of aromatic molecules such as dyes [3]. In the 1870's, Paul Ehrlich proposed the existence of "chemoreceptors", which differed between microorganisms and the host tissue, based on his studies of dyes in biological tissues [3]. He suggested these could be used therapeutically, which eventually gave rise to the development of a class of drug treatments known as chemotherapy.

At the beginning of the twentieth century, pharmacology progressed quickly. In 1905, J. N. Langley introduced the concept of a "receptive substance", the modern basis for the study of receptor agonists and antagonists [4, 5]. In 1933, Meldrum and Roughton identified the enzyme carbonic anhydrase while studying the effects of sulfanilamide, the active metabolite of the antibiotic sulfamidochrysoidine [6]. This discovery led to the concept of enzymes as a good target for drug discovery and gave further importance to the biochemical characterization of cellular functions. Following Alexander Fleming's discovery of penicillin as a product from the *Penicilium* mold that killed *Staphylococcus* bacteria [7], many drug companies invested in microbiology, resulting in the discovery of more antibiotic and other therapeutic agents [3].

Over the next decades, drug discovery progressed along with our understanding of the basic sciences that underlie the discipline of pharmacology. What is currently referred to as interdisciplinary and translational basic science became known as pharmacology and experimental therapeutics. The large explosion of chemical libraries in the 1980's by the large scale implementation of combinatorial chemistry required the simultaneous development of high-throughput screening (HTS) methodologies. With these new technologies, many hundreds of thousands of compounds could be synthesized and then screened against a target of interest. However, this approach was often largely detached from a physiologically relevant screening signal. Another major breakthrough that changed the way society as

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

well as pharmacologists thought about therapeutics coincided with the development of the human genome project in 1986. The hope that a large number of drug targets would soon be identified and, in combination with the HTS technology, that a rapid increase in the discovery of therapeutic agents would result [8] effused through the pharmacology and biomedical sciences community as well as Wall Street aficionados. However, this original optimism met with a declining number of drugs approved by the U.S. Food and Drug Administration (FDA) since 1996, seeming to suggest that a target-based random screening approach was not the panacea originally envisaged for drug discovery.

In this chapter, we will provide a brief overview of some current therapeutic agents, including their weaknesses, and highlight selected opportunities for continued drug discovery efforts in certain disease areas. We will then focus our attention on different strategies used to identify new therapeutic agents, comparing target-based discovery (TBD) and what we refer to as systems-based discovery (SBD). Although pharmaceutical companies have favored TBD during the past thirty years, emerging evidence indicates that SBD may help in solving some of the issues that have plagued the modern approach to drug discovery. Finally, we will explore the challenges associated with the application of SBD to neurological disorders. This chapter is intended neither to be exhaustive or fair and balanced but presents a selective viewpoint. We apologize to those pioneers whose work we may have failed to cite and for simplifications we introduced in the interest of streamlining this chapter.

## 2 CURRENT STATE OF THERAPEUTIC AGENTS AND THE NEED FOR NEW AGENTS

### 2.1 Overview of the Current State of Therapeutic Agents

Therapeutic agents currently on the market can be placed into either one of four categories: small molecules, which are chemically synthesized compounds such as aspirin; natural products, which are small, naturally occurring molecules that are generally isolated from plants, fungi and mold (such as penicillin); biotherapeutics, which are macromolecules that occur naturally (such as insulin and tissue plasminogen activator) or are engineered based upon a biological template (such as trastuzumab (Herceptin, Genentech), a monoclonal antibody designed to treat HER2-positive breats cancer); and nucleic-acid-based therapeutics, which are deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) molecules designed to interfere with the stability or translation of a messenger RNA (mRNA) (such as fomivirsen (Vitravene, ISIS Pharmaceutical and Novartis), an antisense molecule designed to treat cytomegalovirus infections in the retina of immunocompromised patients). The decision to use a small molecule or a biotherapeutic agent is generally dictated by the desired target and, as discussed below, these two classes of therapeutic agents complement each other in terms of their respective capabilities and weaknesses.

***Small Molecules and Natural Products*** For drug discovery, small molecules are typically less than 500 molecular weight (MW) units, although this is not an absolute cut-off as molecules of higher molecular weight could be acceptable if sufficient bioavailability could be achieved. Ultimately, most small molecules are chemically synthesized, but their discovery may be the result of different strategies. Historically, most small molecules were initially isolated from natural products, which is now in disfavored due to the unfavorable logistics of developing commercially viable large-scale chemical syntheses of complex natural products. For example, the compound paclitaxel (Taxol, Bristol-Myers-Squib) was isolated from the bark of a North American yew in the 1960's (Fig 1) [9]. It was later shown to have novel anticancer properties by binding to tubulin, resulting in the stabilization of microtubules and disruption of mitosis [10]. However, the treatment of one cancer patient would have required the harvesting of six yew trees. To address this issue, a synthesis scheme was eventually developed using an analog of paclitaxel,

**Figure 1** Chemical structure of (A) paclitaxel and (B) docetaxel.

10-deacetylbaccatin III (DAB), as starting material (reviewed in ref. [11]). DAB was obtained from the needles of European and Himalayan yew trees, avoiding the harvesting of trees. As shown by this example, isolation of a natural substance may require large amounts of starting material to identify and isolate sufficient quantities of the active ingredient. However, the effort and development costs were clearly justified in this case by the discovery of this life-saving anti-cancer agent. A second and important added value is that the advances in science resulting from the study of natural products may also lead to a drug that acts via a new mechanism and thereby initiate a new area of research on the disease biology.

Iterative modification is a strategy in which novel small molecules are synthesized based upon a well-known template until a novel structure, with improved properties and/or efficacy is obtained. Such an approach can lead to the production of a substantiative patent estate. This is the case with docetaxel (Taxotere), an analog of paclitaxel developed by Potier and colleagues at the Centre national de la recherche scientifique (CNRS) [12] and commercialized by Sanofi Aventis (Fig 1). Docetaxel was identified in a structure–activity relationship campaign where paclitaxel derivatives were tested in a microtubule depolarization assay [12]. In this in vitr*o* assay, docetaxel was about twice as potent as paclitaxel. When compared to paclitaxel in different cell line models of tumor, docetaxel was 1.3- to 12-fold more potent and this was found to be due to docetaxel's higher affinity for microtubules [13]. Further studies using in vivo xenograft models revealed that docetaxel was as effective as or more effective than paclitaxel [14]. In addition, docetaxel treated tumors, such as the C38 colon adenocarcinoma, in which paclitaxel was ineffective. Aside from its higher potency and broader efficacy spectrum, docetaxel is also an improvement over paclitaxel in that it is more soluble [12] and is considered schedule independent [14]. This example demonstrates how structure–activity relationship studies based on variants of a known drug can give rise to novel, improved small molecules.

With advances in the technology for characterization of the three-dimensional structure of proteins, the concept that the design of small molecules could be guided by the structure of the target recognition site(s) emerged. Information required to deduce the structure of the active site and other binding pockets can be obtained using X-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy. Candidate molecules may then be designed to interact with specific amino acids at the desired site of action using molecular modeling, bioinformatics, and computational chemistry. In the final steps of the lead identification process, compounds can be modified iteratively to improve upon or optimized the initial lead's chemical properties, efficacy, and/or potency. This process of "rational drug design" resulted in much enthusiasm during the 1980's and early 1990's but seemed to become incorporated with the platform technology of medicinal chemisty rather than the driving force behind new pharmacological discovery.

The Bcr-Abl kinase inhibitor imatinib mesylate (Gleevec, Novartis) is considered to be the first drug designed rationally [15, 16]. Chronic myeloid leukemia is the result of a reciprocal translocation of chromosomes 9 and 22 which creates a gene encoding for the Bcr-Abl kinase, a highly active tyrosine kinase [17, 18]. The design of a specific Bcr-Abl kinase inhibitor takes advantage of the fact that, although several kinases display sequence homology and similar active conformations, the kinases differ in the conformation of their inactive state [19]. Hence, a specific inhibitor could be designed to stabilize the enzyme's inactive conformation, which is different from that of other kinases, and act by preventing phosphorylation of the substrate(s). The crystal structure of Bcr-Abl kinase bound to an analog of imatinib mesylate appeared to reveal an atomic basis for the specificity of interaction [19]. The compound and Bcr-Abl kinase form a number of hydrogen bonds and van der Waals interactions, which are not possible with other kinases. Interestingly, imatinib mesylate interacts specifically with the inactive conformation of the Bcr-Abl kinase as activation causes a conformational change in the kinase that prevents the drug from binding.

During the development of small molecules therapeutics, optimization is geared toward obtaining a desirable set of physico-chemical properties. At the molecular level, these generally include potency and efficacy and, in most cases, specificity for a particular target. At the level of the whole organism, low toxicity (at an efficacious dose) and adequate pharmacodynamic and pharmacokinetic properties must be achieved. For most therapeutic candidates, the ability of the compound to cross the blood–brain barrier (BBB) and blood–nerve fiber barrier (BNFB) must also be taken into consideration. Nervous tissues are very effectively shielded from endogenous and exogenous molecules, whether centrally or peripherally, through the use of physical, biochemical, and cell biological mechanisms (reviewed in ref. [20]). The endothelial cells lining the intracerebral capillary walls are unusual in that they are connected by tight junctions forming patent zonula occludens and lack fenestrations. In addition, these endothelial cells possess metabolic enzymes and transmembrane transporters that further decrease the penetration of most drugs. Small molecules may cross the BBB with both passive or active mechanisms, as well as vesicular

trancellular mechanisms. For passive transport, the size of the molecule, its lipophilicity and charge ($pK_a$) are the main determinants. Drug candidates with specific functional groups may also be actively taken into the brain via transporters. In some cases, however, BBB integrity may be disrupted, facilitating the penetration of small and large molecules. This is seen most often following pathological conditions, such as stroke, trauma, infections, and neuroinflammatory diseases.

Over the course of the small-molecule development process, BBB permeability may be assessed at different stages by using several methods [20–22]. Computational models have been developed based on known drugs that act in the central nervous system (CNS) (called a "training set"). However, these models are limited by the small size of the training set and by the relatively narrow chemical space it covers [21]. In vivo assays can be conducted in both humans and animals using analysis of pure venous blood, microdialysis, and/or positron emission tomography (PET) imaging [20, 22]. However, these methods are generally low-throughput, labor intensive and costly. The use of in vitro assays, based on cell lines transfected with efflux transporters, was found to be a good complement to previously described methods [23]. It is also important to keep in mind that while BBB permeability is critical for drugs acting in the CNS, it is also an advantage to reduce the BBB permeability of drugs targeted outside of the nervous system to decrease potential CNS-mediated side effects. This is the case for loperamide, a therapeutic agent used to treat diarrhea [24]. Loperamide is a peripherally acting μ-opioid receptor agonist targeting receptors located in the large intestine. Because it does not cross the BBB, loperamide is devoid of analgesic properties usually observed with BBB-permeable μ-opioid agonists such as morphine.

Unfortunately, many drugs are marketed without providing doctors and patients information about BBB permeability and possible neurological side effects. An example of this situation is provided by the aromatase inhibitors (AIs), used to reduce the recurrence of estogen-responsive breast cancer, either in conjunction with or following treatment with tamoxifen [a selective estrogen receptor modulator (SERM) acting as an antagonist in breast tissue]. AIs work by inhibiting the aromatase (also called CYP19), the enzyme responsible for producing estrogen. Three AIs are currently the market: the non-steroidal agents anatrozole (Arimidex, AstraZeneca) and letrozole (Femara, Novartis), and the steroidal compound exemestane (Aromasin, Pfizer). Aromatase is present in several tissues including adipose tissue, uterus, bones and brain. While a reduction of estrogen levels in adipose tissue is critical to prevent the resurgence of breast cancer, studies also suggest that estrogen may be important for maintaining cognitive functions [25]. Hence inhibiting estrogen production in the brain may lead to cognitive decline. Strikingly, no information regarding cognitive function following chronic AI treatment is provided to the physicians or patients, even though these drugs were approved over 8 years ago. Studies regarding the possible effects of AIs on cognition in breast cancer patients have only been recently initiated, and, although preliminary results are beginning to come out, the numbers are still too small to determine whether there is an effect (reviewed in ref. [26]). If one or more of the AIs were known to be BBB impermeable, doctors and patients may be able to make a better informed decision regarding the treatment choices and quality of life.

Small molecules may be active at intracellular, extracellular, or both locations of targets and, as such, have traditionally been the platform of choice to act on enzymes and receptors. Moreover, depending on their physico-chemical properties, small-molecule drugs have been designed to be orally bioavailable, which greatly facilitates administration and patient compliance.

***Biotherapeutics*** A biotherapeutic has thus far been considered to be a protein that works by mimicking the action of a naturally occurring substance. In many cases, the therapeutic was no more than the endogenous protein that was produced by a different method, for example, insulin produced synthetically using recombinant DNA technology as compared with purified insulin. Historically, protein therapeutics were isolated from human or animal sources, and their use carried risks such as variable efficacy, contamination by resident infectious agents, and immunological reactions. Most biological therapeutics are now manufactured using recombinant DNA technologies, allowing for a reliable and consistent product [27]. Immunogenic reactions to biotherapeutics are still a concern, but the added level of safety that is derived from a more chemically defined preparation justifies the approval as adverse reactions can be managed in most cases [28].

Recombinant protein therapeutics developed on the heels of the revolution in the area of molecular biological technologies. In 1972, the first article describing the use of restriction enzymes to cut two viral DNAs was published [29], and, by 1978, Genentech, the first company founded to develop biotechnologies, had expressed human recombinant insulin in *Escherichia coli* (*E. coli*) and produced about 20 ng of purified protein [30]. This joint venture with the pharmaceutical giant Lilly resulted in clinical trials beginning in 1980, and in 1982 human insulin manufactured by fermentation of *E. coli* became the first recombinant biotherapeutic to be approved by the FDA.

Over the years, recombinant therapeutic design has evolved and most protein therapeutics that are on the market are not exact duplicates of their endogenous human counterpart. For example, amino acid substitutions are sometimes included to improve pharmacokinetic properties [28]. In other cases, mutations may be induced to change a protein's function. Pegvisomant (Somavert, Pfizer) is a growth hormone receptor antagonist used to treat acromegaly (reviewed in ref. [31]). Substitution of 1 amino acid in the human growth hormone's 191 amino-acid-sequence is enough to turn this agonist into an antagonist. To create pegvisomant, eight other residues were mutated, increasing binding affinity to the receptor, and polyethylene glycol molecules were added to promote stability of the antagonist. Interestingly, even with modifications recombinant protein therapeutics are generally well tolerated and, for the most part, do not trigger immunological complications [28].

The use of antibodies as therapeutic agents has also emerged as a new technology. The success of immunization as a method to protect against infectious agents such as the measles and rabies virus stimulated thought that polyclonal antibodies isolated from human or animal serum could be used to combat toxins and venoms as well as to protect against infections. When this approach was tried, hypersensitive reactions were often triggered because the immune system recognized these polyclonal antibodies as foreign agents that needed to be removed. The advent of monoclonal antibody (mAb) production techniques in the 1970's, along with molecular biology, paved the way for the development and production of chimeric mAbs (murine Fv fragments linked to human IgG Fc fragment), humanized mAbs (human antibody except for the antigen-binding region, which is derived from mouse), and fully human mAbs (derived either from human B cells or from transgenic mice expressing human IgG). Although the immunogenicity of these mAbs is reduced, adverse reactions are still observed in some patients even with fully human antibodies, requiring coadministration of an immunosuppressive agent such as methotrexate (reviewed in ref. [32]). At the molecular level, antibodies may neutralize or antagonize the target, act as agonists, or deplete the target protein from the blood supply. The specific therapeutic action against a target is determined in part by the location of the epitope and by the constant region of the antibody. The ultimate pharmacological success of the therapeutic will require not only biological efficacy but a constant region that minimizes the induction of clearance, complement-dependent cytotoxicity, and antibody-dependent cellular cytotoxicity or apoptosis.

The development of a biotherapeutic for rheumatoid arthritis (RA) treatment provides a good example of the challenges associated with mAb therapeutics [32]. RA is a chronic disease caused by a complex pathology that involves the release of pro-inflammatory cytokines, such as tumor necrosis factor-α (TNF-α), and leads to the destruction of cartilage and bones of non-weight-bearing joints. A major difficulty associated with the use of mAbs is that animal models and ex vivo assays (such as whole-blood assays) offer limited predictability for human efficacy and adverse reactions. For example, at least eleven different antibodies against the T-cell surface antigen CD4 have been developed that are well tolerated and reverse autoimmunity in animal models. However, these same mAbs lacked clinical efficacy when tested in humans. The lack of equivalence between animal models, including non-human primates, and human subjects can sometimes have unexpectedly serious consequences. The activating, anti-CD28 mAb TGN1412 (CD28 SuperMAB, TeGenero Immuno) was shown to be extremely effective at reducing autoimmune reactions without apparent side-effects in both rodent and non-human primate models [33]. However, when TGN1412 was administered to healthy human subjects, all 6 volunteers developed multi-organ failure and extreme cytokine activation. It is unclear whether this reaction could have been otherwise predicted, but it emphasizes the differences between animals and humans when it comes to the pharmacological effects of antibody-based therapeutics.

In contrast to T-cell-directed agents, biological therapeutics targeting TNF-α have been very successful. FDA-approved agents include the anti-TNF-α chimeric mAb infliximab (Remicade, Centocor) and the humanized mAb adalimunab (Humira, Abbott). Both are well tolerated and produce immunogenic reactions in a very small fraction of patients, especially when taken with methotrexate. Another interesting agent is the fusion protein etanercept (Enbrel, Amgen/Wyeth), which is composed of the extracellular domain of the p75 TNF-α receptor attached to the hinge and constant domains 2 and 3 of the human IgG1. This biological therapeutic acts by binding TNF-α, reducing its concentration in blood and preventing its binding to the endogenous TNF-α receptors.

In addition to their traditional roles as immune modulators, antibodies can also be engineered to act as carriers designed to deliver a toxic "warhead" to specific target cells, such as in cancerous tissue. For this application, a specific mAb is conjugated to a toxin, small molecule, or radioisotope that is designed to selectively kill the targeted neoplastic cells [34]. This approach, in principle, allows the the accumulation of a high local concentration of active toxic compounds while minimizing side effects. For example, $^{131}$I tositumomab (Bexxar, GlaxoSmithKline), which binds to CD20, is used for the

treatment of refractory non-Hodgkins lymphoma [35]. The CD20 antigen is present on normal and malignant B cells, including on 90% of B-cell non-Hodgkins lymphomas. Following a single infusion of $^{131}$I tositumomab, 68% of patients saw improvement in their pathological and clinical profiles, including 33% who showed a complete response (Bexxar product information, GlaxoSmithKline).

The large-scale development of biotherapeutics is hindered by the limited options for drug delivery. Due to their large size and susceptibility to degradation in the gut, these agents must be administered via injections or by implantable control release devices. It is also currently impossible to use biotherapeutics for the treatment of disorders of the nervous system due to the fact they lack BBB and BNFB permeability. However this issue may be resolved as pre-clinical studies have been conducted using molecular Trojan horses; that is, fusion proteins between molecules that cross the BBB via receptor-mediated transport and BBB-impermeable agents (reviewed in ref. [36]). In those experiments, peptides such as the vasoactive intestinal peptide, and ribonucleic acid (RNA) interference (RNAi) against the epidermal growth factor (EGF) receptor were successfully delivered to the brain parenchyma. However, further studies will have to be conducted to determine the applicability of this method of biotherapeutic drug delivery to human nervous tissue.

***Nucleic-Acid-Based Therapeutics*** The latest new category of therapeutic agents to emerge, in the 1990's, was based on nucleic acids. The early drug candidates in this group took advantage of antisense sequences as a method to specifically inhibit translation of a given gene product. Although the exact mechanism of antisense inhibition is not fully understood, it is believed that hybridization of a short, single-stranded DNA or RNA sequence complementary to an mRNA targets that mRNA for degradation and/or prevents the ribosome from binding to the mRNA, resulting in decreased levels of protein product. Administration of antisense could be used to treat a variety of conditions such as viral infections, cancers and disorders caused by a mutant protein exhibiting a gain-of-function. However, there are also numerous challenges associated with these therapeutic agents including the short half-life of oligonuclotides in biological fluids, their cellular uptake, and the toxicity they may induce [37]. Chemically modified bases can be used to increase stability of the antisense oligonucleotides in vivo. The most common is the phosphorothioate deoxynucleotide, which increases serum half-life from 1 hour for standard oligonucleotide to 9–10 hours for phosphorothioate-containing oligonucleotides. Cellular uptake can be improved by using delivery systems composed of lipids, polymers or nanoparticles. An alternative strategy is to conjugate the antisense oligonucleotide to an antibody or ligand recognizing a receptor on the surface of the cell, achieving targeted delivery. Toxicity is often the result of an off-target effect(s) and needs to be assessed on a case-by-case basis [39].

The first and only FDA-approved antisense oligonucleotide to date is fomivirsen (Vitravene, ISIS Pharmaceutical and Novartis). This therapeutic agent received approval in 1998 to treat cytomegalovirus-induced retinitis in AIDS (acquired immunodeficiency syndrome) patients (reviewed in ref. [38]). Fomivirsen is composed of phosphorothioate deoxynucleotides and is administered intravitreally. However, although this medication answered a specific medical need, the small number of patients and low sales lead Novartis to discontinue its production. Several other antisense therapies have entered clinical trials, but none have demonstrated sufficient efficacy to obtain FDA approval [37].

RNA interference (RNAi) is a method endogenously used by a wide variety of organisms to target mRNA molecules for degradation [40–42]. Unlike antisense-mediated inhibition, the mechanism by which RNAi works is well understood, and several putative therapeutic agents at different stages of development make use of this technology [43, 44]. RNAi can be achieved using micro-RNA (miRNA), small interfering RNA (siRNA) or short hairpin RNA (shRNA). miRNAs are endogenously encoded single-stranded RNAs that interact with the 3′ untranslated region of mRNAs. Since they do not require perfect sequence homology, miRNAs can interact with 100–200 genes, some of which may be involved in the same signaling pathway [43]. Inhibition of a given mRNA by miRNAs is not complete, but additive effects may be observed if several transcripts in the same pathway are targeted by one miRNA. Endogenous miRNAs, such as miR-146, miR-155 and miR181a, are involved in the development and regulation of the immune system and are altered in chronic inflammatory diseases [45]. In addition, miRNA changes have been reported to correlate with the progression and prognosis of certain cancers [43]. These observations suggest that miRNAs may be an interesting therapeutic target.

The other two types of RNAi tools, siRNAs and shRNAs, are exogenously applied to modify gene expression [46]. siRNAs are short (19–23 nucleotide) double stranded RNAs with a perfect complementarity to their target mRNA. Once they enter the cell, they are taken-up by the RNA-induced silencing complex (RISC) which unwinds the siRNA and degrades the sense strand. The antisense strand is then used as a template to identify the target mRNA, which is then degraded by Argonaute-2. A good siRNA can mediate >90% inhibition of its target. A number of siRNAs are

currently in clinical trials [43]. While naked siRNAs may be appropriate for targeting easily accessible tissues such as the eye or the lung, they are not stable enough to be delivered via systemic circulation. For deeper tissues such as the kidney, chemical modifications and/or delivery systems are used [43]. The most advanced siRNA, currently in phase III clinical trials, is bevasiranib (Opko) against vascular endothelial growth factor. It is a naked siRNA administered by intravitreal injection for wet age-related macular degeneration. AKIi-5 (Quark/Silence) is a chemically modified siRNA that targets p53 and that is delivered intravenously. It recently began phase I trials for acute renal failure.

As their name indicates, shRNAs are short, single stranded RNA sequences that form a hairpin. In the cytoplasm, this hairpin is cleaved by Dicer, leading to an siRNA that can interact with the RISC as described above. The advantage of shRNAs is that they can be encoded on a viral vector, which can be engineered for tissue-specific and/or controlled delivery (reviewed in ref. [47]). A variety of vectors have been used successfully in animal models, including adenoviruses, adeno-associated viruses (AAVs), and lentiviruses. Two shRNAs recently entered clinical trials, targeting hepatitis B infections (Nucleonics/Novosom) and AIDS-related lymphoma (Benitec).

RNAi methods are not without risks and challenges. The most common issue observed in animal models has been the risk of saturation of the endogenous RNAi machinery. For example, in mice receiving large doses of one of 49 different AAVs encoding for shRNAs against 6 different genes, 36 constructs led to liver toxicity, including 23 which resulted in death [40]. This was shown to be due to saturation of Exportin-5, a transporter for precursors of siRNAs and miRNAs. This serious problem can be avoided by using naked siRNAs (mature siRNA enter the RNAi machinery downstream from Exportin-5) or by using a lower titer of virus. Viruses engineered to offer controlled expression of their transcript may also be useful, representing a significant opportunity for the development of new therapeutics.

Using RNAi may also cause off-target effects and/or trigger an interferon-mediated response. Both of these can be reduced by chemically modifying the siRNA and by avoiding specific sequences, which are known to be immunogenic. Finally, resistance to a particular RNAi may develop as a single base-pair mutation is enough to disrupt the interaction between an siRNA and its target. This may be avoided by engineering a vector with a few different shRNAs against the same target.

***Portrait of Drug Approval in Recent Years*** Most new drugs authorized by the United-States Food and Drug Administration (FDA) are classified as small molecules, whereas biotherapeutics account for 5–29% of the yearly approvals (Fig 2). However, despite technical advances and increased spending in research and development by pharmaceutical companies [48], the number of drugs approved has been declining since 1996. This effect is particularly noticeable for small molecule

**Figure 2** Drug approval by the Food and Drug Administration (FDA) since 1996. (A) Number of new drugs approved per year by category. Small molecules (gray bars) require the submission of a new drug application (NDA), while biotherapeutics (black bars) are reviewed under the form of a biological licence application (BLA) (Data source: www.fda.org.) (B) The drug approval differential, as compared to the number of drugs approved in 1996, reveals that there has been a progressive decline in approvals in the past ten years. In the last few years however, rate of decline seems to be leveling off. (C) Despite stabilization in the number of new drug approvals, the cumulative drug approval differential suggest that if approvals had been maintained to the level of 1996, we would have nearly 300 additional new drugs on the market today.

therapeutics. There are many reasons for this trend, including increased requirements for safety, reduced side-effects, and a litiginous system of law [39, 49]. Given the current risks and elevated cost of developing a new drug, pharmaceutical and biotech companies often turn to repurposing, the identification of new indications for existing drugs, or to reformulation, such as developing continuous release or combination therapies, to increase their market share [49, 50].

If the outlook for new drug discovery at large is declining, the glacier trail leading to breakthrough neurotherapeutic agents is even more daunting and treacherous. According to the World Health Organization [51], 40 million people worldwide are affected by epilepsy, 24 million suffer from Alzheimer's disease or other forms of dementia, 62 million are diagnosed with cerebrovascular diseases, and 326 million suffer from migraine. However, despite the high prevalence of these disorders, only a few drugs with neurological indications are approved each year (Fig. 3). Clearly, therapeutic agents targeting neurological conditions must cross the BBB, but it is estimated that 98% of putative neurotherapeutics fail due to lack of BBB permeability [52]. In addition, candidates often fail during clinical trials due to poor efficacy or safety concerns. As expected, CNS-directed agents tend to cause CNS-mediated side effects such as seizures, dizziness and nausea. Moreover, the lack of validated biomarkers makes it difficult to assess whether the drug reaches concentrations that are sufficiently high at the target to be efficacious [53]. In 2006 alone, 11 drug programs targeting 7 neurological disorders were halted during clinical testing [54]. In the current situation, there is a dire need for new therapeutics directed towards even the most common of neurological conditions. It is sobering to note that with all of its undesirable side effects and adverse reactions morphine, and its derivative opiate receptor agonists, still provide the mainstay of analgesics.

**Figure 3** Number of new drugs approved by the FDA from 2003 to 2007 with a primary indication for a neurological disorder or neuropathic pain. Small molecules are indicated by gray bars and biotherapeutics by by black bars. The only biotherapeutic recently approved is natalizumab (Tysabri, Biogen/Elan), an anti-α4 integrin monoclonal antibody used to treat relapsing multiple sclerosis (Data source: www.fda.org.)

## 2.2 Need for New Therapeutic Agents

Over the last century, there have been major advances in our understanding of pharmacology, biology of disease, and in methods for the discovery of therapeutic agents toward a wide range of maladies. Indeed, the discovery of the "wonder drugs", the tricyclic antidepressants, phenothiazine antipsychotics, and benzodiazepine anxiolytics, completely changed the way society thought about mentally ill: from the notion of insanity and incarceration to the concept of neurological disorder and outpatient treatment. However, there is a great need for continued research and development to improve existing therapeutics, develop new classes of pharmacotherapies for diseases where the current treatments may not work in some or even most patients, and to establish new treatments for conditions where none are available. Given the decrease in new drug approvals in the last several years, it is important to emphasize that there is a crucial need for more new therapeutics to be developed and submitted for review. In order to improve its productivity, not only must the pharmaceutical industry rethink its drug discovery strategies but the federal government and international world health agencies must work to provide an optimal setting for the high risk high stakes business of drug discovery and development to thrive.

***Improving on Currently Existing Therapeutics*** It is easy to imagine the properties of the ideal drug: orally bioavailable, once a day treatment, with no side effects, and completely effective in all patients. Improving on existing therapeutics is an important and valuable method to generate new therapeutics. This strategy mitigates the risks associated with first-in-class therapeutic agents as the chemical genres and target are often well-validated, and certain aspects associated with modulation of the target in humans have been explored. Among the improvements that are generally feasible are enhancements in efficacy, and/or potency, and/or specificity, all aimed at enhancing desired as compared with undesired pharmacological effects via altered pharmacodynamic and/or pharmacokinetic properties. Incremental improvements on the method or frequency of delivery can also provide significant benefits to patients and thus justify the allocution of limited resources to such objectives.

However, this is not a safe haven for the pharmacologist as any modification can cause deleterious side effects even if the discovery effort focused on the creation of a new therapeutic agent acting on the same

target as the approved drug. Novelty is also a key aspect of new drug design, whether small molecule or biotherapeutic, as patent protection is an essential element to commercialization. While this driver is often bemoaned, it serves a useful purpose in rewarding pharmaceutical companies that bring breakthrough science to the benefit of medicine via the market place.

***Finding New Targets for Conditions Where Therapeutic Agents Already Exist*** An exciting and challenging direction is to discover a new therapeutic agent that acts at a novel target that improves the treatment relative to a medication that already exists. The target can be selected from within a pathway that has already been exploited or in a different pathway that is also important for the disease biology. In addition to resolving intellectual property issues identified with the previous strategy, this approach offers a number of advantages. For example, a drug acting at a different target may be effective in non-responders to existing therapeutics due to a number of factors, such as tolerance, heterogeneity of disease pathology, or variations in genetics among populations. A therapeutic agent with a new mechanism of action is also likely to have a different side effect profile, which may be better tolerated. However, working on a new target brings risks that are usually not a factor when working with a known target. For example, choosing a target which is involved in multiple biological pathways or whose biological role(s) is(are) poorly understood may lead to unanticipated adverse events, such as previously described for the super-agonist anti-CD28 mAb TGN1412 [33], or the breakthrough discovery of the selective cyclooxygenase-2 (COX-2) enzyme inhibitor rofecoxib (Vioxx, Merck). It is, therefore, sobering to realize that the particular target must be chosen carefully and thoroughly validated to ensure that it is both implicated in the therapeutic pathway and unlikely to produce serious adverse effects when its activity is modulated. In this regard nature is unforgiving and while patent law rewards novelty, the best science may not always be rewarded. As an example, while Merck scientists discovered a selective COX-2 inhibitor rofecoxib, a number of adverse events that would result from selective inhibition of this enzyme were not anticipated. Inhibition of the COX-1 enzyme was deemed responsible for the gastro-intestinal bleeds observed following chronic treatment with non-steroidal anti-inflammatory drugs (NSAIDs). Pfizer developed the less selective and therefore seemingly less innovative drug celecoxib (Celebrex), which inhibits mainly COX-2 at a therapeutic dose with minimal effects on COX-1 [55]. Although mechanistically similar, rofecoxib was voluntarily withdrawn yet celecoxib has remained a specialty pharmaceutical with a black box warning. This teaches us that the objective of developing a highly potent selective inhibitor of one of two enzymes in a pathway firmly implicated in a physiological process is sound but the side effects that result from involvement of a particular target in other patho-physiological processes can surface as well.

Combination therapy using two or more classes of therapeutic agents to treat a disorder can also provide substantial benefits with reduced risks. This approach has helped with the management of human immunodeficiency virus 1 (HIV-1) infections, for which there are currently six different classes of drugs available. According to the U.S. Department of Health and Human Services, initial therapy with two or three antiviral agents is most effective at reducing HIV-1 load since infected patients often present with a small proportion of viruses harboring drug-resistant mutations [56]. Upon resurgence of the viral load, a new drug combination can be used to suppress infection by a resistant virus strain.

In addition to delaying the appearance of drug-resistant viruses or cancer cells, combination therapy may also be useful to increase the efficacy of a treatment by co-administering two drugs which are not completely effective when given alone. This strategy is often use for the treatment of hypertension, where single agents may not sufficiently lower the patient's blood pressure [57]. Another possibility is to combine two therapeutics at a sub-optimal dose to reduce side effects and achieve increased efficacy. One example is the combined use of acetaminophen with an opioid receptor agonist such as oxycodone. Acetaminophen reduces the dose of the narcotic analgesic required and thus reduces the adverse side effects, limitations, and liabilities for both. However, de novo side effects or undesirable events may arise. These may result from interactions of the different drugs with liver metabolizing enzymes, competition for transport mechanisms, or biological interactions between the different targets and pathways modulated. For example, in prescription drug narcotic addiction, addicts learn that pulverizing controlled-release oxycontin tablets provides a rush by circumventing the controlled-release formulation. Consumption of large amounts of acetaminophen/oxycodone can also result in chronic overdose of acetaminophen, possibly resulting in severe kidney damage.

***Finding New Therapies for Untreated Conditions*** Perhaps the greatest challenge, and the greatest need, in drug discovery resides in finding therapeutic agents against disorders for which no treatment exists. Factors influencing the decision to launch a new drug discovery program include unmet medical need, market size, the ability to diversify the company's intellectual property

portfolio, the availability of required technical expertise, the prospects for upcoming competitors, and the anticipated level of difficulty with the new drug approval process [27]. Although pharmaceutical companies generally focus on a disease that affects a significant portion of the population, there has been a trend in the United States for smaller biotech companies to work on orphan drugs, designed to treat rare disorders affecting less than 200,000 Americans [49]. In addition, for therapeutic agents that treat serious medical conditions where there is an unmet medical need, a priority application can be filed with the FDA, which accelerates the approval process and reduces the total time to market. In recent years, the proportion of priority applications approved by the FDA has risen in comparison with standard approvals (see www.fda.gov), suggesting that this avenue may be advantageous for both medical and commercial reasons.

The identification and validation of a target remains a major challenge with developing a drug for an untreated condition. This is especially true if the disease biology is poorly understood. While the recent emphasis by the pharmaceutical industry has been on identifying a single target and creating a highly potent and specific drug, examples taken from older "dirty" drugs and combination therapies show that drugs acting on multiple subtypes of a single target group or on multiple targets can be highly beneficial. One example is the non-selective benzodiazepine positive modulator diazepam which acts on at least twelve different γ-aminobutyric acid ($GABA_A$) receptor subtypes containing the $\gamma_2$ subunit. Another example is the double reuptake inhibitor venlafaxine (Effexor, Wyeth), which inhibits both norepinephrine and serotonine transporters.

## 3 APPROACHES FOR DRUG DISCOVERY

Historically, drug discovery began with the empirical observation of a therapeutic effect, often by random testing in animals, which was then confirmed and further refined using bioassays and preclinical models (Fig 4).

**Figure 4** Drug discovery pipeline. The discovery of new a therapeutic can be initiated in a number of ways as illustrated here by the historical approach, target-based discovery (TBD) and systems-based discovery (SBD). Although the first step (first box for each method) differs, the lasts steps of the process leading to optimization and development of the compound, pre-clinical, and clinical trials are fairly similar. In the case of SBD, the nature of the initial screening system dependent on the disease studied. For example, while cancer and inflammation can be modeled accurately using a collection of human cells, neurological disorders may require a more complex system such as an *in vivo* recording model in order to obtain data from neural assemblies. Neural assemblies are units of neurons whose activity, when taken together, contributes to the observed behavior. Interestingly, although the approach proposed for systems-based drug discovery seems to be similar to the historical approach, our improved understanding of the disease biology today facilitates the selection of an appropriate model for screening compounds, eliminating the need for a trial-and-error approach and increasing our chances for success. It is assumed tha for SBD, the input of compounds would not necessarily involve HTS but could begin with high value focused chemical libraries.

Today, in the postgenomic era, there has been a change in paradigm. Drug discovery is now usually initiated by the identification and validation of a target, even before any putative therapeutic is tested. While this was an effective strategy in the late 1980's and early 1990's, the trend towards decreasing new drug approvals during the past decade raises questions about the long-term effectiveness of this approach. In addition, to overcome challenges associated with the increased scrutiny from regulatory authorities and the ever-rising cost of development for new therapeutic agents, the industry may consider revising its functional model for drug discovery, by transitioning from a target-based approach to a systems-based or combined approach.

In the sections below, we review current drug discovery strategies and suggest a number of opportunities for advances based upon existing needs for improvement.

### 3.1 Target-Based Discovery (TBD)

Target-based discovery is the most widely used strategy by pharmaceutical and biotech companies. Although specific details may vary, the general framework of TBD is usually similar across companies (Fig 4). The first step is to identify a target that is important to the onset or progression of disease pathology [58]. As part of this process, the "druggability" of a putative target, that is, whether and how such a target could be modulated by a therapeutic agent, is of key strategic importance [59]. In addition, financial considerations, public perception of a disease, and governmental health policies may also affect the target selection process [60]. Previously validated targets are an obvious choice, as discussed above, but information regarding novel targets may be obtained from various sources. In some cases, human genetic associations identify a chromosomal area or specific gene that is linked to the disease and further associated based upon a valid animal model [58]. If no suitable target can be identified from in vivo studies, in vitro methods including activity assays and gene or protein expression studies may provide useful information. Alternatively, in silico methods such as bioinformatics (genomics, proteomics, transcriptomics) and pathway analysis may allow to rapidly identify potential targets, but these will require additional validation [61]. It is important to note that results from all the above-mentioned methods may also be found in the literature. Although targets identified from the literature are not technically novel, because the knowledge is publicly available, they can present a lower risk profile if they emerge from high-quality data.

The next step in TBD is to validate the targets identified. This is a crucial step in that it provides the foundation for the entire drug discovery program. Failure to properly validate a target may cause the program to fail at later stages when much time and financial ressources have already been invested. To establish a validated target, several criteria must be fulfilled [58]. When comparing patients affected by the disease and healthy controls, a good target may have a different expression level or activity level. However, interpretation of data such as a change in protein levels or activity may reflect either the cause of the disease or the consequence of the disease. Changes could also result as an adaptive self curative process. In the later case, inhibition of a molecule involved in a negative feedback pathway may worsen the disease. As part of the validation process, the expression pattern of the target molecule must be assessed and localized in a tissue that is relevant to the pathology. Clearly, the ultimate step in target validation is to demonstrate that modulating the target in human patients improves their condition. This is a demanding task but of great importance. New technologies and/or strategic approaches that advance the validation of the target function in human disease will be on the cutting edge for years to come.

As its name suggests, TBD is based on finding drug candidates that act specifically at the chosen target. In the pre-exploratory phase of drug discovery, the assays that are going to be used to test drug candidates are developed, and the specific assays chosen depend upon the type of target. For example, enzyme targets can be tested conveniently in isolated protein assays [62]. However, to find a drug modulating a G-protein-coupled receptor (GPCR), a functional screen in a cell-based assay may be more appropriate. This approach could employ a focused chemical library of a small number of compounds and lower throughput high value screens, such as high throughput electrophysiology [63], or high throughput screening (HTS) of large scale compound libraries.

For the HTS approach, the first step precludes washes and requires an output that can be measured easily [64]. Secondary assays of increasing order of complexity are conducted following the HTS screening. These assays utilize automated benchtop technologies, can be more detailed, but should still have a throughput that is high enough to screen thousands of hits from the HTS screen. The secondary assay phase can employ a cell-based assay, if not already carried-out in the primary assay, and includes selectivity screens. Assessing selectivity early-on is critical as off-target effects may induce side effects or adverse events in pre-clinical studies.

Following in vitro assays, short-term in vivo assays are performed. These assays can usually be carried out on the time-scale of hours to 1 or 2 days and require less compound. Although they may not be a good predictor of efficacy in the disease model, they allow

a determination as to whether the compounds can have some effect when introduced into an animal. Pharmacokinetic studies establish the dosage and route of administration to be employed in the long-term in vivo studies using animal models of disease. At the end of the pre-exploratory phase, an established screening tree beginning with target-based screening and ending with selective pre-clinical animal models of disease is fully implemented.

Once the assays to test the activity of compounds at the target have been established, the TBD exploratory phase can be initiated. The objective of this phase is to identify hits from a library of compounds, and then from those hits to generate one or a few lead families of compounds. Following HTS, thousands of potential hits may be identified [64]. If structural information is available on the target or on a known ligand of the target, pre-screening of the library using structure-based computer modeling may help decrease the total number of hits and increase hit quality [61, 64]. Compounds identified by HTS then have to be re-screened and/or counter-screened to confirm their activity and establish a basic dose–response curve. After confirmation, hits are subjected to the secondary assays devised during the pre-exploratory phase. Following each assay, compounds are ranked and structure–activity relationships (SAR) and structure–property relationships (SPR) emerge. These relationships help to better understand how the compounds work and how they can be improved using chemical modifications [65]. A few hits are generally selected to undergo iterative rounds of chemical modification and testing in secondary assays. At this point, one or a few lead series are typically chosen to move on to the next step.

For each lead series in the discovery phase, the SAR and SPR would be further characterized, pharmacokinetic/pharmacodynamics (PK/PD) studies performed, and candidates tested in in vivo models. It is interesting to note that for TBD this is the first phase where chemical entities are actually introduced in animals. As a result, compound production must be scaled-up to achieve a medium scale [66]. PK studies are important to establish the time-course for drug absorption, distribution, metabolism and excretion [67, 68]. As part of the metabolism studies, possible interactions between the drug and the hepatic cytochrome P450 (CYP) family of enzymes are tested. Drug-mediated inhibition of a CYP enzyme that is responsible for the metabolism of the compound studied or of other commonly used therapeutic agents may lead to severe side effects or to drug–drug interactions [68]. Given the possible severity of the consequences of CYP inhibition, such occurrence would be carefully evaluated. PD studies, on the other hand, relate the pharmacological and toxic effects observed upon administration of a drug to the concentration of its active metabolite in the plasma (or other tissue of interest).

Throughout this process, chemical modifications are still being performed to improve the compounds' properties and to address any potential issues that could result in failure to identify a lead compound. The information obtained from the PK/PD studies is critical for the subsequent in vivo studies as the dosage and dosing frequency selected need to provide an adequate drug concentration for the appropriate duration to obtain a therapeutic effect with minimal toxicity [69]. Animal studies begin with the short-term models devised during the pre-exploratory phase, which have a faster readout and require less compound. Then, the more promising candidates are tested in the long-term disease models. While in vivo testing is present throughout the discovery phase, determination of the efficacy of a compound in a disease model is not done until the later part of this stage and, although chemical optimization is ongoing, there is a risk that the lead(s) obtained may fail and be unsalvageable.

When a lead compound or compounds is/are identified, further testing in non-human primate models including PK, PD, proof-of-concept, and efficacy in a disease model are carried out. This last testing phase allows to obtain information which may be more indicative of the drug's effect in humans, although some unpredicted events may still occur later on in the clinical trials. If a good TBD lead candidate is obtained, drug development can begin.

As described, TBD is a lengthy process with a general progression from the simplest, most reductionist models towards the more complex systems. In parallel, iterative rounds of chemical modifications are performed to establish SAR and SPR in an attempt to improve the compound properties and resolve problems that may arise. While TBD has been successful in identifying new drugs against previously validated targets (i.e. modulated by a known drug), generation of therapeutic agents acting at novel targets has been disappointing [70]. This can be explained in part by the fact that although TBD leads to compounds whose mechanism of action and contact sites with the target are reasonably well-understood, it is also prone to late-stage failures as testing in more relevant in vivo models is not done until the end of the discovery process. This creates an unfortunate situation where, by the time an advanced compound is rejected, several years of discovery and huge opportunity costs have already been invested in the project without any return.

### 3.2 Systems-Based Discovery (SBD)

As the limitations of TBD described above become evident, an alternative view of drug discovery is emerg-

ing. Systems-based discovery (SBD) methods are based on the use of complex systems that model the disease to look for potential therapeutic compounds, instead of focusing on simpler assays that test drug interactions with a single target (Fig 4). While SBD might in some way seem to be a return to the traditional approach to drug discovery, recent technologies allow for the automation of high content assays, with a concomitant increase in throughput. However, advances in computational modeling facilitate the identification of pathways and mechanisms important to the disease biology [70, 71].

A range of systems could be suitable to use as the starting point for SBD. Human cell systems offer many advantages and provide a practical approach to SBD [70]. The complexity of the pathways involved in a disease may be modeled better using a combination of human cell types instead of a cell line. Rather simple modifications can also be made to a human cell system to reflect different physiological or pathological states, further increasing the chances of uncovering therapeutic properties for the drugs tested. For example, a model system for studying inflammatory diseases could be composed of endothelial cells and blood mononuclear cells, stimulated using a combination of cytokines [70]. A disadvantage of such a system, however, is that it may be difficult to obtain the correct combination of primary human cells that will meaningfully reflect the biology of the disease. Some conditions, such as psychiatric disorders, may not be amenable to cellular-level modeling while others, such as these regulated by organism-wide hormonal signaling, may only be modeled crudely by a human cell system. However, new stem cell technologies may remedy this deficiency by providing an endless supply of undifferentiated tumor cells and tissue components.

Another advantage of SBD compared to TBD is that drug screening is performed using a marker of disease progression/regression so there is no procedural requirement to identify and validate a target which, in principle, could reduce discovery costs by allowing only higher value molecules to be identified as leads. Moreover, although target validation in animal models of disease is widely accepted, a given target overexpresed in a cellular or non-cellular system may select for molecules that work in an animal model but are not as relevant to the disease pathology in humans or target modulation may cause unexpected adverse effects. SBD screens compounds against an unknown number of targets but would theoretically generate relatively advanced hits.

Following system-based screening, further testing is conducted and the promising compounds are optimized. As previously described for TBD, these assays include PK and PD characterization as well as short- and long-term animal models. At this stage, a lead compound may be obtained. If desired, target deconvolution strategies can then be applied to identify the target or targets that is/are modulated by the lead compound (specific examples of deconvolution techniques are reviewed in ref. [72]). However, these methods depend upon a physical interaction between the lead compound and one or more targets, with varying affinities and efficacies. Target deconvolution can be straightforward to intractable and should be considered optional as clinical trials can be initiated if safety and efficacy have been demonstrated in cell-based and animal models of the disease [70].

A more complex alternative to the use of human cell systems is to generate system response profiles [73]. These can be obtained by subjecting samples such as body fluids or biopsy samples to various analyses (gene array, mass spectrometry, NMR spectrometry, immunoassays, etc) to obtain levels of gene transcripts, proteins, or metabolites. System response profiles can then be compared across healthy and sick individuals or before and after administration of a therapeutic compound, for example. By collecting samples at different time points, an analysis of the system's dynamics can also be performed. This extracts information about disease progression and/or provides a better understanding of the transient effects of a therapeutic agent. System response profiles may help identify sub-groups of patients with a given diagnosis that are expressing different biochemical markers.

For a systems pharmacology assessment, such a classification may also provide biomarkers for drug discovery and help predict which patients are likely to respond to a given treatment. This application alone could help increase the success of clinical trials, especially for neurological disorders where the lack of validated biomarkers has been cited as a cause for the high rate of failures, due to possible improper patient classification and difficulties in assessing the suitable amount of drug to use [53]. In a different application, system response profiles may be useful in assessing the validity of an animal or cell-based model of the disease [74]. By comparing the system response profiles of the disease model to that of human patients, it may be possible to determine which pathways hold predictive validity and are more likely yield a successful therapeutic agent. Furthermore, different models may be better predictors for different subgroups of the patient population.

Golub and colleagues developed a similar system, called the Connectivity Map, using data collected from treating human cells with a variety of biologically active compounds [75]. This publicly accessible database can be searched for information regarding the activation of certain genes following the treatment of cultured human cells with drugs. By comparing different profiles a new biological function for a known compound can

be identified. Gene expression-based high-throughput screening (GE-HTS) has been used to screen for inhibitors of platelet-derived growth factor receptor (PDGFR) signaling [76]. PDGFR signaling leads to activation of the extracellular regulated kinase (ERK) pathway, which is known to be up-regulated in a number of cancers. In human TIP5 fibroblast cells treated with PGDF with or without an ERK inhibitor and subjected to microarray, a number of regulated genes correlated with ERK activation were selected as markers for ERK inhibitor activity. Application of GE-HTS to a chemical library led to the identification of aurintricarboxylic acid, which inhibits PGDFR phosphorylation, preventing downstream activation of ERK. GE-HTS does not require a detailed knowledge of the signaling transduction cascade and captures molecules that act either upstream or downstream of the known kinase.

When applied during clinical trials, system response profiles may also generate useful information and potentially rescue drug candidates that would otherwise fail [73]. For example, the system response profiles of drugs with limited efficacy could be used to predict useful therapeutic combinations, either with a previously marketed agent or with another low-efficacy drug. System response profiles may also help to better understand mechanisms by which drugs work, including potential off-target effects. These unknown mechanisms can either enhance therapeutic effects or cause side effects. Knowing which disease pathways are targeted by a given treatment may also expose unexploited areas of the disease profile, including potential new drug targets.

Despite these limitations and given their potential benefits, system response profiles could fulfill the need for the discovery of new therapeutic agents by delivering higher value lead candidates earlier in the discovery process.

### 3.3 Balancing TBD and SBD

TBD and SBD offer very different strategies, as illustrated by the dissimilarities in their workflow pipelines (Fig 4). In TBD, the first discovery milestone identifies and validates a drug target. By contrast, SBD begins with the development of a systems-level assay representative of the disease and then proceeds with testing a library of compounds to identify hits. With TBD, assay development and hit generation occurs later in the process, following target identification and validation. SBD generates hits at an earlier stage and, at least theoretically, selects compounds that have better druglike properties. Whereas TBD uses simple and usually cell-free assays for HTS, SBD is generally carried-out using an intact cell assay on a system ideally composed of human cells. The quality of the hits obtained plays a major role in determining how much effort will have to be devoted to lead identification/optimization. Another major difference between the two strategies resides in the fact that in TBD, compounds are tested in cell-based systems during the discovery stage, which occurs much later in the process as compared with SBD, which begins with a cell-based system or tissue. In concept, compounds identified by HTS in TBD fail at a much later stage than those from SBD. Given these differences, one may think that, on average, SBD would generate more higher quality leads in a shorter time span. However, this may be counter balanced by the fact that additional efforts will have to be devoted to identify the target(s) modulated by the SBD lead compound. This last step is useful from the point of view of understanding how a given compound works, but it is not required to fully understand the mechanism of action of a drug in order to obtain permission to test it in humans. The prerequisites for a compound to enter clinical trials are demonstrated efficacy and safety in animal models of disease. As can be seen from this discussion, the development of a systems-based approach to drug discovery is in its infancy and represents an emerging need for new technological approaches.

Once an optimized lead compound is obtained, the remainder of the process to obtain a new therapeutic agent is similar between TBD and SBD, even though outcomes may be different. In both cases, drug candidates need to be tested in animal models of the disease. In addition to being ready for the preclinical phase faster, leads obtained via SBD may act on several targets. In contrast, leads from TBD are, in principle, selected to be effective at and selective for a single molecular target, although side effects exerted via actions at multiple unanticipated mechanisms is common. While modulation of a single target may be sufficient to treat a disease, cellular pathways are often resistant to perturbations [77], and drugs acting at several targets may be more successful. For the development phase, TBD and SBD converge. At this post-discovery stage, there are major differences between the preparation of small molecules and biotherapeutics. The development phase is the last stage before the drug is tested in humans. It consists in establishing manufacturing conditions to produce the compound and conducting any additional pre-clinical studies that may be needed. It is also in this phase that the clinical trials are planned. This requires determining the population to be tested, establishing protocols and planning for centers to conduct the trials. When this is done, an Investigational New Drug Application can be filled with the regulatory agency. This document details the findings obtained in in vitro and in vivo studies, with particular emphasis on

safety and efficacy, and the plans for clinical trials. If there are no concerns on the part of the regulatory agency, clinical trials are allowed to begin.

Administration of a test substance into humans is a highly regulated process whose details are beyond the scope of this chapter. However, to summarize the process, clinical trials are divided into three phases. Participants in each phase are required to sign an informed consent form detailing the potential risks and benefits associated with their participation in the trial. In phase I clinical trials, a small number of healthy subject are recruited to test the safety of the investigational new drug. The first PK/PD studies are also conducted during this stage. If no adverse events are reported, the study then proceeds with phase II. At this stage, varying doses of the drug are tested in an intermediate number of patients afflicted by the condition studied. These studies may also be conducted with a group of control patients receiving a placebo (with or without the standard approved treatment). The objective of phase II trials is to establish an efficacious dose and dosing regimen for the drug. In phase III, the drug is tested in a large number of patients across different geographical areas in a double-blind, placebo-controlled trial. The objective of this phase is to establish efficacy in a demographically diverse patient population. The large number of subject recruited may also help in identifying unforseen events occurring in only a small fraction of the population, which may have been missed in phases I and II due to the small sample size. Following the completion of the phase III studies and if the drug is deemed safe and efficacious, a New Drug Application (for a small molecule) or a Biological License Application (for a biotherapeutic) is filed with the regulatory agency to obtain the permission to commercialize the new therapeutic agent. As compounds enter clinical trials, it is thought that the SBD pipeline would be more successful on average due to early selection for activity in complex animal and/or human cell systems leading to the optimization of low toxicity hits targeting several members of a pathway or even different pathways involved in the disease.

### 3.4 Brief Look at SBD in the Context of Neurological Disorders

***Inherent Difficulties Related to the Study of the Nervous System*** For a successful application of SBD, a suitable animal model with objective and appropriate biomarkers must be established. When considering the molecular basis of a disorder, this may seem at first glance to be a fairly straightforward task as many molecular signaling cascades are conserved across the animal kingdom. For example, the components of the janus kinase (JAK)-signal transducer and activator of transcription (STAT) signaling pathway signaling pathway, which has been involved in a variety human diseases including brain cancer, neuronal injury following stroke, and depression in rheumatoid arthritis patients, can be found in the nematode *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster*, and in the fish *Danio rerio*, as well as in mammals such as mice, rats and monkeys [78–80].

However, the structure and/or functional domains of proteins may also diverge during evolution with important consequences for disease biology. As an example, mutations in the human leucine-rich repeat kinase 2 (LRRK2) gene have been associated with an autosomal-dominant form of Parkinson's disease (reviewed in ref. [81]). Although *Drosophila* and *C. elegans* both express LRRK, their gene lacks an N-terminal repeat compared to the human LRRK2, which occurred later in evolution [82]. Studies the endogenous LRRK protein in these animal models, therefore, may not be appropriate to further our understanding of the role of LRRK2 in healthy humans and in those afflicted with Parkinson's disease. This is a good example of a protein that acquired additional functional domains during evolution, and these new functional domains may be important for the biological basis of a disease. It follows that the development of new therapeutics for the treatment of Parkinson's disease would reasonably focus on LRRK2 rather than LRRK if TBD were used. With SBD, the function of LRRK in the context of systems biology could correlate with the function of LRRK2. If true, and if a valid system approach could be conceived of, results from a lower organism could be used, perhaps in combination with TBD. Alternatively, it is possible that addition of new functional domains on a protein would affect its signaling and/or protein–protein interactions, in which case the pathway in which this specific protein is involved would need to be studied for SBD.

One example of an SBD strategy to streamline discovery for neurological disorders would be to pre-screen the initial chemical library to reduce its size and to begin the drug discovery process by using a hybrid approach that incorporates elements of TBD. Since 98% of compounds do not cross the BBB [52], performing an initial BBB screen on the entire chemical library would result in a focused library for neurological applications. Then, using knowledge of the molecular basis of a particular disorder, to the extent that it exists, some target-based screening might also be valuable. For example, positive modulation of a selected group of $GABA_A$ receptor subtypes by certain benzodiazepines and related therapeutics reduces anxiety in a safe and effective way. But all produce side effects such as drowsiness and sedation that limit their usefulness for day time anxiety. Whereas

the search for a selective anxiolytic free of sedative-hypnotic side effects has been driven by a TBD approach based upon $GABA_A$ receptor α2 subunit selectivity (reviewed in ref. [83]), ocinaplon was found to be a non-sedating anxiolytic in human subjects but surprisingly, relatively non-selective towards the α1, α2 and α3 subunit-containing $GABA_A$ receptors [84].

In the search for new anxiolytics, a hybrid approach in which BBB-permeable compounds are screened for activity against the benzodiazepine-responsive $GABA_A$ receptor subtypes could be effective. Instead of focusing on subtype selectivity as in TBD, compounds identified through HTS could be tested using the SBD approach. Following animal toxicity studies and phase I clinical trials, compounds that are likely to be effective in humans could be identified using system response profiling. It would seem that the search for new treatments for anxiety disorders and other neurological disorders would benefit greatly from future improvements in technologies for high-resolution analysis of nervous system function that are applicable to the intact human brain and spinal cord. Using these technologies nervous system responses in patients and normal controls could be generated. Drug candidates could then be evaluated in a small number of subjects using focused clinical trials to identify lead compounds that bring the patient's nervous system response profile toward that of a normal control. This approach would likely yield compounds acting on multiple targets but may improve future success rates.

Expanding the scale to a specific group of cells or an anatomical region containing a physiological pathway that is known to correlate with or be critical in the disease biology could be used. For example, the development of new therapeutic agents in the area of cognitive enhancement would fulfill an important unmet medical need. The hippocampus and parahippocampal region of the medial temporal lobe are well known to be important for declarative memory, the type of memory involved in remembering places, time, and events, as well as the emotions associated with these situations. One of the most famous examples for the association of the medial temporal lobe with declarative memory is provided by H.M., a patient with intractable epilepsy, who had his parietal temporal lobe surgically removed bilaterally in 1953 [85]. While H.M.'s seizures became manageable, he suffered severe anterograde amnesia, with partial retrograde amnesia, making him unable to complete episodic or semantic memory tasks, both of which are part of declarative memory (reviewed in ref. [86]). However, his short-term memory and ability to acquire new motor skills remained intact. Subsequent lesion studies in monkeys and rodents have confirmed the importance of the hippocampus and parahippocampal region for declarative memory, although the specific role of each individual anatomical region within the medial temporal lobe remains controversial (reviewed in ref. [87] and [88]).

Divergences in studying declarative memory across species may be explained in part by evolutionary divergences in the anatomical structures involved. Looking across mammalian species, the hippocampus appears to be well conserved both in its anatomical organization and in the intrinsic connections between its cornu ammonis (CA) field and dentate gyrus [89]. However, small variations can be observed in the parahippocampal region, and further disparities are found in the neocortex, which provides input to the hippocampus via the parahippocampal region. These differences may arise from connectivity patterns, cortical size and/or laminar stratification. Hence, if sensory information coming to the hippocampus from the neocortex differs across species, it is a strong possibility that the behavior of the animal, influenced by the hippocampal output, will also differ.

While some behaviors, such as recollection of previous events, may differ somewhat between species, other demeanors are strictly human and even more difficult to model in animals. An example of such behaviors found in schizophrenia, which includes positive (hallucinations, delusions, thought disorders), negative (anhedonia, lack of emotion and motivation, catatonia), and cognitive (attention and memory impairments) symptoms [90] that have yet to be reproduced in a comprehensive animal model. Models currently used can be classified as either predictive if they can be used to predict the therapeutic ability of a drug; or partially homologous if they can recapitulate some of the symptoms observed in humans [91]. One criticism associated with using predictive models is that they may miss drug candidates acting via a novel mechanism because these animal models are established and validated using currently available therapeutics. In addition, predictive models may be using behavioral assessment that represents only a minor problem in schizophrenic patients [91]. In the case of partially homologous models, in the absence of a better understanding of the disease biology of schizophrenia, it is difficult to assess whether treating the symptom(s) or objective responses represented in the animal model will truly yield an effective therapeutic in human patients.

Identification of new therapeutics for neurological disorders poses a problem in that there is often a lack of evolutionary conservation in the biological processes involved. While this can be solved at the molecular level by studying the human components involved in a pathway, it is difficult to establish a convincing parallel between information obtained from animal models in rodents and non-human primates and the results obtained in clinical trials. Furthermore, as shown in

**Figure 5** A systems pharmacology view of a platform for drug discovery in the nervous system. (A) The systems used for drug discovery can be arranged by increasing organization level. (B) Example of an adaptation of the organization level scale for drug discovery oriented towards neurological disorders. Although drug discovery programs may start at different steps of the process outlined here, a number of adaptations must be made when going from one model to the next. (C) There are a number of differences even between the human and macaque brain. PALS (population-average, Landmark, and Surface-based) rendering of the macaque and human brains are shown along with functional areas defined by Lewis and Van Essen [94]. Based on the localization and size of those functional areas, a map of cortical expansion can be designed. (Reproduced from ref. [92].)

Figure 5, discrepancies can arise at multiple levels, making it even more difficult to find an accurate animal model, even in species such as the macaque which is closely related to the human.

***On the use of Integrative Databases as a Tool to Facilitate SBD for Neurological Disorders*** Since the use of animal models is essential to drug discovery and development, one SBD approach would be to track and record differences and similarities between subregions of the nervous system of different species. This includes their wiring diagram at strategic developmental stages depending upon the disorder to be treated. This neural systems-level information on circuitry could then be linked to anatomical information with functional data such as electrophysiology, behavior, functional magnetic resonance imaging (fMRI), gene expression and neurochemistry. Since there is a need to represent a

**Figure 6** Example of a brain atlas. Anatomical and functional information may be displayed on a flat map (reproduced from ref. [97].)

large amount of annotated anatomical information, databases referred to as multimodal brain atlases have emerged (Fig 6) [92]. Electronic brain atlases offer several advantages over print atlases in that they provide a dynamic link between structure and function, which is easily accessible, searchable, updated and linked to other databases and resources [93]. In addition, whereas traditional atlases were based on post-mortem studies of one or a few brains, multimodal atlases incorporate information from MRI and allow the creation of population averages and probabilistic analysis.

There are a number of databases currently available which may help in the application of SBD to neurological disorders. Human and macaque surface-based brain atlases using flat images and/or 3-dimentional reconstructions (reviewed in ref. [93]) are derived mainly from imaging studies, while other databases include different types of information. The Allen Brain Atlas provides a comprehensive analysis for the expression of 20,000 genes in the brain of adult (post-natal day 56, P56) male mice [95]. Searches in this freely available online atlas provide images from in-situ hybridization, annotated for major brain structures, and links for the gene or protein of interest in other databases. The GenePaint Atlas also provides information on gene expression in the mouse brain but includes brain from different developmental stages [96]. Although the number of genes covered is smaller than that of the Allen Brain Atlas, information on spatio-temporal expression of genes can be especially important for developmental disorders such as autism and schizophrenia. In addition, the database is updated weekly, and researchers can submit requests for candidate genes [98].

Another issue frequently encountered when studying a developmentally regulated process is the "conversion factor" between the brain of two species. To address this question, Clancy and colleagues used neuroinformatics to translate brain development data across 10 species including mice, rats, cats, macaques and humans [99]. Since different brain regions mature at different times in different species, this program further allows to compare two animals for cortical events, limbic events, and non-cortical/limbic events. In the context of SBD, this would help establishing a valid animal model for developmentally regulated processes and diseases.

## 4 CONCLUDING REMARKS

The science of pharmacology has progressed tremendously since its inception. Microbial infections that were once fatal can now be treated with antibiotics and other conditions for which there is still no cure, such as type I diabetes and certain breast cancers can be managed in many patients using a number of approaches including the appropriate medication. However the promise of a horn of plenty filled with new biology "wonder drugs" based on modern discoveries of pharmacology com-

bined with advances such as the sequencing of the human genome remains at the end of the rainbow. One could even wonder whether the outlook for the development of breakthrough therapeutics does not look grim with the continued decrease in yearly new drug approvals over the past decade combned with increased legal, social and political pressure. To resolve this issue, the pharmaceutical industry may need to bring a shift in its drug discovery and development strategies, whether it is for the generation of new small molecules, biotherapeutics, or nucleic-acid-based therapeutics and/or more productive focused clinical trials. Although TBD has seemed, in theory, the way to increase efficacy while reducing side effects of new therapeutics, a look at the current rates of success and failure for new drug candidates, as well as their associated costs, seems to suggest otherwise. An alternative approach, as suggested here, would be to consider enhancing SBD strategies within the drug discovery scheme. This may reduce the fraction of drug candidates that have inadequate efficacy and/or induce significant side effects, decreasing the average cost of discovery and development that accrues as drugs emerging from company pipelines fail pre- and postmaketing. At the same time it is possible to generate compounds that act through novel mechanisms or via combined actions at several targets. Similarly, a polypharmaceutical approach in which a novel combination of approved therapeutics may be identified by SBD provides practical advantages if the screening process could be shown to yield substantially higher value lead therapeutic combinations. However, the application of SBD may be particularly challenging in certain diseases where it is difficult to accurately represent the spectrum of symptoms observed in humans within an animal model. To remedy this, an important objective for R&D is to identify better biomarkers for disease progression, develop a better understanding of cross-species differences and, based on this information, to develop more valid animal models that can be monitored using the same biomarkers carried through to clinical trials.

Nowhere is the disconnect between human disease and animal models for disease more apparent than for those disorders based upon dysfunction of the nervous system. As just one example, the nervous system challenges biomedical science to break the barrier of disconnect between the anxiety perceived by the patient with generalized anxiety disorder and the animal models for it, using biomarkers in order to guide discovery. Regardless of the approach taken, efforts must be made to diversify the treatment options available and to provide new therapeutics for conditions where there is a medical need. For many neurological disorders, such as schizophrenia and depression, treatment options are associated with severe side effects and are effective in only a fraction of the population, whereas in other conditions, such as Alzheimer's and Parkinson's diseases, therapeutics only reduce somewhat the appearance of symptoms in some patients. Whereas therapeutics exist for the treatment of anxiety disorders, convulsive disorders and sleep disorders, the existing treatments are palliative and burdened with untoward side effects. In addition, there is no treatment available for a number of neurological diseases including spinal muscular atrophy, a hereditary motor neuron disorder. While the nervous system is complex and presents with additional challenges, such as the BBB and the BNFB, which are absent in other organs, it is critical that efforts be invested in this area to overcome this lag in the development of new therapeutic agents. It is our hope that advances in SBD, combined with biomarker development, validated animal models for diseases, and enhancements in the design, surveillance and interpretation of clinical trials will lead to the discovery of therapeutic cures rather than palliative treatments for disorders and diseases that afflict us.

## 1 BACKGROUND

Aside from very early interests in optical rotation as well as rotatory dispersion and circular dichroism (CD), "optical activity" of chiral molecules has motivated chemists and physicists for some time (1). Pertinent for the purpose of this article is that optical activity can arise from *electronic* transitions, which normally occur in the *visible* and *ultraviolet* spectral regions, or from *molecular vibrations* observed in the *infrared* (IR) region. Of specific interest in the text to follow are the differences in absorption between left and right circularly polarized light. Known respectively as *electronic* circular dichroism (ECD) and *vibrational* circular dichroism (VCD), both

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing,*
Edited by Shayne C. Gad
Copyright © 2011 John Wiley & Sons, Inc.

techniques are useful and unique spectroscopic tools. The interest in VCD in particular has mushroomed during the 1970s resulting largely from endeavors of researchers at the Universities of Minnesota (G. Holzwarth), Southern California (P.J. Stephens), Chicago (T.A. Keiderling), and Syracuse (L.A. Nafie) from which a truly remarkable and relatively rapid development followed. Discussions in the context of the essay to follow will be restricted to discoveries and applications since the turn of this century assuming that the earlier information is reasonably well documented, known, and understood.

Upon perusing pertinent literature citations, it will be clear that VCD represents the difference in absorption intensity of left versus right circularly polarized radiation most commonly in the infrared region and particularly between 800 and 2000 $cm^{-1}$. Although this limitation is not absolute, the VCD signals of molecular vibrations in this region are those most pertinent and prominent. The vibrational modes within this region are largely skeletal distortions, be they stretching or bending modes. Cyclic molecules therefore are the most interesting targets but not exclusively so. For this reason as well, favorite molecular systems for investigation are a plethora of biological molecules that perform myriads of important functions. Among these are such highly interesting and pertinent molecular components as DNA, RNA, and proteins in addition to individual drug molecules all of which usually contain one or more cyclic components. Fortunately, and although some of the pioneering investigators managed successfully often with home-built instruments, VCD spectrometers are now available from several manufacturers.[a] One can therefore expect the use of VCD to grow at a goodly pace.

In support of this prediction, one needs to mention only a few examples of applications, including relatively simple measurements of VCD data for several synthetic polyribonucleotides (2), VCD studies of the A-to-B conformation transition in DNA (3), B–Z conformational transitions of DNA including *ab initio* interpretations of VCD spectra (4), determining absolute configuration and solution conformation of materials such as gossypol (5), vibrational circular dichroism spectroscopy and the effects of metal ions on DNA structure (6), determining solution conformations of cyclosporin complexes (7), DNA–oligonucleotide–cisplatin binding (8), and many more. Pertinent aspects of these and other systems will be discussed in greater detail below. Of particular interest, impact, and utility for this article is a recent publication in which the authors provided a detailed description of progress in vibrational optical activity for determining structural properties of pharmaceuticals (9). Last but not the least, the general term "optical activity" also includes Raman optical activity (ROA) for which Barron et al. (10) have provided interesting and pertinent examples; however, this topic is not included in the text to follow.

[a] PMA 50 accessory in conjunction with the Tensor™ series FT-IR (Bruker Optics), Chiral*IR*™ (BioTools), Nicolet™ FT-IR coupled with PEM module (Nicolet Thermo), FVS-4000 vibrational CD spectrometer (JASCO), and Varian 7000 FT-IR spectrometer with Hinds PEM.

# 2 GENERAL DESCRIPTION

## 2.1 Vibrational Circular Dichroism

VCD is a chiroptical spectral method, which while similar to its analogs, optical rotatory dispersion (ORD) and ECD, discriminates between enantiomers because of their differential response to left versus right circularly polarized light. While ORD is due to the difference in the refractive indices that cause different propagation velocities of oppositely polarized radiation components through chiral media (circular birefringence), CD, either electronic or vibrational, originates from different absorption of polarized light by chiral molecules. Primarily, circular dichroism was measured in the ultraviolet and visible spectral range where the presence of a chromophore is required to detect electronic transitions. Vibrational circular dichroism is caused by $3N - 6$ vibrations of the atoms in a molecule and is related to transitions between distinct vibrational levels.

## 2.2 Instrumentation Methods

The VCD spectra are measured as the difference in absorbances for left and right circularly polarized radiation by a chiral molecule as defined by Eq. 1:

$$\Delta A = A_L - A_R, \tag{1}$$

where $A_L$ and $A_R$ are the corresponding absorbances. The values of $A_L$ and $A_R$ are to a great extent alike, which makes their difference quite small and usually three to four orders of magnitude smaller than either one of them. The detection of such weak signals poses substantial challenges for the VCD experiment. The experimental measurement requires decomposition of the electric vector of incident linearly polarized radiation into left and right circularly polarized components that are further allowed to irradiate the sample. This can be achieved by introducing phase retardation of 90° ($\frac{1}{4}\lambda$) between these components. Three distinct physical approaches have been employed so far for this purpose, namely, the photoelastic modulator (PEM), polarizing Michelson interferometer, and total internal reflection. At present, photoelastic modulation remains to be the only practically usable method. Phase retardation is attained by periodical mechanical stress applied to an isotropic IR transparent crystal. As a result, the crystal becomes birefringent; for example, the polarized radiation components will travel with different speeds through the crystal. An additional yet substantial benefit that follows is the retardation, which is modulated between two states with phase difference of 90° (left and right circular polarization) in accordance with the applied mechanical stress. Thus, the sample is irradiated by polarized light alternating between left and right circular polarization and resulting in a differential interferogram registered by the detector. The light modulation ensures the desired *ac advantage* for measuring very small differences between absorption signals of nearly even amplitudes. A drawback of the method is that the optimal circular polarization is obtained only twice during the sinusoidal cycle of the applied

stress and for one wavenumber only. Apart from that, the radiation is elliptically polarized, which reduces the efficiency of the modulator.

In the polarizing Michelson interferometer (11), the conventional beam splitter is replaced by an IR polarizer, which serves to separate the components of the polarized beam. The phase modulation is attained at Fourier frequencies and is limited by the speed of the scanning mirror. Although this method circumvents the spectral limitations of the photoelastic modulation, it is unsuitable for routine applications because of long data acquisition times and accompanying instrumental drift.

Phase retardation could also be attained by means of total internal reflection. In order to reach 90° retardation at a certain azimuth of the incident polarization and definite refractive index of the totally reflecting element, it is only necessary to switch between $+45°$ and $-45°$ angles of incidence. Such a retarder, *Fresnel rhomb*, which is highly achromatic in the entire IR range, has already been used in dispersive (12) and FT spectrometers (13). Without modulation, the spectra are of low signal-to-noise (S/N) ratio and show persistent artifacts. This method still has unexploited potential and would allow for VCD measurement in the whole mid-IR range provided that proper modulation between the opposite polarization states is ensured.

The photoelastic modulation remains the most advantageous method when selected spectral intervals are to be scanned; all commercially available instruments offered by different manufacturers are based on this principle. Some Fourier transform spectrometers operate with double modulation, the interferogram being modulated once at Fourier frequencies and thereafter at PEM frequency. A typical scheme and optical design of a FT-VCD spectrometer used in essentially all modifications is shown in Fig. 1.

Among the commercially available spectrometers, only BioTools Inc. currently offers completely stand-alone instruments, where the VCD optics is incorporated and prealigned into the spectrometer. Other manufacturers, such as Bruker Optics, Nicolet Thermo, Varian, and JASCO, provide VCD modules that can be attached to standard FT-IR spectrometers. The IR beam from the interferometer is first linearly polarized

***FIGURE 1*** *Optical scheme of VCD setup.*

by a wire-grid polarizer and then enters the PEM. The polarizer is set at 45° with respect to the modular axis of the crystal to allow equal amplitudes of linearly polarized light to reach the orthogonal stress axes of the crystal (ZnSe) driven at 37 kHz. The modulated circularly polarized light passes through the sample positioned adjacent to the PEM and focused with a ZnSe lens onto an HgCdTe detector. The proper choice of a narrowband and low-noise detector is essential for the measurement. A long-wave pass optical filter placed either in front of the polarizer or in front of the detector stops the radiation above 1800 $cm^{-1}$. The low spectral range is limited by the ZnSe optics and a detector whose cutoff is about 800 $cm^{-1}$. These precautions preclude detector saturation in the wavenumber region where the PEM has low efficiency. The detector signal is preamplified and then divided into two paths. While the first path is directly fed to the analog-to-digital (A/D) converter (Fig. 1), the signal passes through several electronic devices in the second path. The signal is first filtered by a high-pass filter to remove the Fourier frequencies, thereafter demodulated by a lock-in amplifier tuned to the modulation frequency, passed through a second filter to remove any residual "dc" signal, and then fed to the A/D converter. The first path measures the ordinary sample interferogram usually designated as "dc". The second path yields the differential interferogram of the sample denoted as "ac". Fourier transformation generates the corresponding single beam spectra $I_{ac}$ and $I_{dc}$, and their ratio defines the raw VCD spectrum (14):

$$\frac{I_{ac}(\tilde{\nu})}{I_{dc}(\tilde{\nu})} = 2J_1[\alpha_0(\tilde{\nu})]\exp[-(2V\tilde{\nu})\tau](1.1513)\Delta A_{LR}(\tilde{\nu}). \tag{2}$$

The raw VCD spectrum is directly related to the difference in the absorbances, $\Delta A_{LR}(\tilde{\nu})$, and is thus expressed in arbitrary units. $J_1[\alpha_0(\tilde{\nu})]$ is the first-order Bessel function and represents the efficiency of the PEM at a definite wavenumber $\tilde{\nu}$ and maximum retardation $\alpha_0(\tilde{\nu})$. The exponential term characterizes the attenuation factor of the lock-in amplifier, where $V$ stands for the speed of the scanning mirror and $\tau$ is the time constant of the lock-in. The coefficients and hence the true absorbance values can be determined by a suitable calibration procedure in which the sample is replaced by a quarter-wave plate with a second polarizer behind it. The quarter-wave plate, whose fast axis is set parallel to the stress axis of the PEM, transforms the circularly polarized light back to linear, which is analyzed by the second polarizer. The calibration procedure involves measurement of two VCD spectra, one in which the analyzer is parallel to the first polarizer and the second in which it is perpendicular. Both VCD spectra are displayed in Fig. 2.

The connection of the intersection points with straight lines produces the calibration plot, which visualizes the efficiency of the circularly polarized light. Dividing the raw VCD by this curve and substituting the time constant of the lock-in yields the true VCD spectrum in absorbance units. One more adjustment is necessary for routine application of VCD. The phase correction algorithm of Mertz implemented in standard IR software for Fourier transformation can be troublesome for VCD spectroscopy since it accounts for positive peaks only. The negative peaks are often folded into the positive domain, which leads to erroneous results. This uncertainty can

***FIGURE 2*** *Calibration spectrum. The straight lines connecting the intersecting points show the efficiency of the circularly polarized light.*

be avoided either by employing a modified phase correction algorithm (15) or by transferring the phase correction from a stressed optical plate, which produces a monosignate VCD spectrum (16).

Further advance in VCD instrumentation has been achieved by implementing the dual polarization modulation method (17). It involves introducing a second PEM directly after the sample and operating at slightly different frequency. The VCD spectrum is measured separately and in parallel at each frequency of the two PEMs. The modulated beam intensities reaching the detector are demodulated simultaneously by two lock-in amplifiers and then subtracted electronically in real time. The subtraction eliminates artifacts that are caused by birefringence since they appear to be nearly equal for both PEMs, while VCD remains unaffected. The proposed method needs precise electronic adjustment but helps to eliminate the influence of linear birefringence, which distorts the baseline of the VCD spectrum. In this way, the VCD spectra can be measured without the need for background measurement.

## 2.3 Uniqueness and Applicability of Results

All chiral molecules whose IR absorption spectra have sufficient intensity in solution should show measurable VCD. Nonetheless, there is no direct correlation between IR absorbance and VCD intensities. As VCD is sensitive to molecular conformation in solution, the molecules that possess multiple conformations of nearly even populations might show much weaker VCD signal than those with one prevailing conformation. To the last category belong bicyclic molecules similar to most terpenes, which have rigid structures due to their fused rings. α-Pinene and camphor have generally been adopted as the qualitative measure for the performance of a VCD spectrometer.

***FIGURE 3*** *Absorption (bottom) and raw VCD (top) spectra of neat (−)-α-pinene, 40% (v/v) in $CCl_4$ in 0.15 mm NaCl cell. The VCD spectrum is a result of 500 ac and 25 dc scans collected on a modified Bomem MB100 spectrometer, 4 $cm^{-1}$ resolution, and 0.4 mm/s mirror speed (18).*

Nonetheless, α-pinene is more frequently used because it also enables sampling as a neat liquid. Both molecules show strong VCD signals and yield good S/N ratios at relatively short measurement times. The VCD spectrum of (−)-α-pinene together with the corresponding absorption spectrum is presented in Fig. 3 (18).

The raw VCD spectrum is the result of 500 ac scans and 25 dc scans, which comprises about 10 min data acquisition time. Since the VCD band intensities are much smaller than those of absorptions, and consequently the VCD intensity scale is much expanded, the subtle baseline distortions due to optical imperfections may become visible (Fig. 3). As a result, the baseline of the VCD spectrum deviates from its zero value and needs to be corrected. The usual way to make this correction is to measure the VCD spectrum of the opposite enantiomer taken at precisely the same experimental conditions. The subtraction of the two spectra and the division of the result by 2 yields the enantiomer corrected spectrum. This subtraction effectively eliminates the noise, which has a random character, while the VCD bands remain

***FIGURE 4*** *(a) IR absorption and VCD spectra of (+)-α-pinene and racemic (±)-α-pinene. (b) IR absorption (bottom), enantiomer corrected VCD (middle), and noise estimate (top) of neat (+)-α-pinene. Both VCD spectra were acquired with 20 min data acquisition time (18).*

unchanged. The opposite mathematical operation on the two spectra determines the VCD zero line and is referred to as noise estimate. It should represent the "VCD" spectrum without the sample in the instrument's optical train. The same result has to emerge when the sample is a racemic compound or simply the spectral solvent. Examples of raw VCD spectra of (+)-α-pinene and racemic (±)-α-pinene are displayed in Fig. 4 (18).

Some deviations persist in the baseline of racemic α-pinene, where the strongest absorption bands occur. These deviations cannot be compensated for also in the noise estimate of (+)-(α-pinene (Fig. 4). These distortions occur noticeably in the wavenumber range where the photoelastic modulator is less efficient and consequently the VCD bands are less intense. The main sources for the baseline distortions are polarization and absorption artifacts. The first of these two reasons is inherent for each particular spectrometer and the optics used in the VCD setup. The polarization artifacts appear as weak "VCD" bands typically in the spectral range where the sample does not absorb. The artifacts arise from optical arrangements and some imperfections in the optical elements. Particularly with our instrument, the imperfections were due to reflections from the internal ledges of the sample cell holder as well as residual stress and birefringence left in the detector window. It is known that reflections from metal surfaces as well as passing through birefringent material may cause phase shifts of the incident polarized radiation. While the reflections from the sample holder can be avoided either by inserting an aperture in front of the cell or by using mild focusing of the IR beam, the second reason is difficult to circumvent. The residual stress left in the crystal can depend on the manufacturing process and on the type of the crystal. Baseline distortions due to

residual birefringence can be partially compensated for by repositioning the optical filter in front of the detector or by rotation of the ZnSe lens.

## 3 APPLICATIONS

### 3.1 Determination of Enantiomeric Purity and Enantiomeric Excess

The abundance of one enantiomer over another in a chemical substance is known as enantiomeric excess (ee). Enantiomeric excess is defined by the respective concentrations of both enantiomers according to Eq. 3:

$$\mathrm{ee} = \frac{c_R - c_S}{c_R + c_S} \times 100\%, \tag{3}$$

where $c_R$ is the concentration of the $R$ enantiomer and $c_S$ is the concentration of the $S$ enantiomer. This equation can be used for ee assay provided the amount of each enantiomer produced is known. Mixing two enantiomers will show net optical rotation unless it is a racemate. Since the optical rotation is proportional to the concentrations of each enantiomer, it can be used for assaying enantiomeric purity according to Eq. 4:

$$\mathrm{ee} = \frac{[\alpha]_\lambda^T}{[\alpha]_{max}} \times 100\%, \tag{4}$$

where

$$[\alpha]_\lambda^T = \alpha / lc \times 100 \tag{5}$$

is the specific optical rotation of the sample at a given wavelength $\lambda$ and temperature $T$. $\alpha$ is the measured angle of optical rotation, $l$ is the thickness of the polarimetric cell, and $c$ is the solute concentration; $[\alpha]_{max}$ is the specific optical rotation of the pure enantiomer measured at exactly the same conditions as $[\alpha]_{max}$ of the sample.

Historically, this is the oldest method for enantiomeric purity assay and is routinely applied for ee evaluations. Some shortcomings are typical for this method. They are related to difficulties with reproducibility because optical rotations are sensitive to concentration, solvent, temperature, and traces of impurities with high optical rotation. Furthermore, polarimetry cannot accurately and reliably establish the enantiomeric purity of a sample unless the optical rotation values are calibrated by an independent method.

NMR spectroscopy with chiral shift reagents is one of the simplest and most accessible techniques available for determining enantiomeric purity. The method consists of adding to the sample a chiral lanthanide reagent, which shifts some of the NMR bands. If the corresponding peaks of each enantiomer can be resolved, the

percentage ratio of the enantiomers can be measured as relative peak heights or areas. Although routinely applied, NMR with shift reagents has limited applicability for analyzing enantiomeric purity. Among the drawbacks are finding suitable shift reagents. In addition, difficulties may arise when substances with several chiral centers are to be investigated.

The most frequently applied technique for enantiomeric excess is high-performance liquid chromatography (HPLC) using chiral columns. Enantiomers are affected differently by the chiral substrate in the column and appear at different retention times. The ratio of the band areas of the separated enantiomers is the basis for the ee evaluation with accuracy reaching 0.1% ee when complete separation is possible (19). The chiral columns are, however, expensive and sometimes inefficient when complex mixtures are to be separated. The chiral stationary phases are specific to chemical functionalities that require maintenance of several types of columns for relatively small ranges of optically active compounds. Combining HPLC with UV and/or chiroptical detection can improve the quantitation and detection limits in unfavorable cases when complete separation is not possible (19). Such a combination is particularly useful for online monitoring of asymmetric syntheses when the reaction steps can result in racemization of the product. Analyses of reaction mixtures are usually maintained by reverse-phase HPLC. The combined use of UV and CD detectors can help identify impurities that are not chiral or detectable by CD detectors, but the extent of racemization cannot be determined (19). In addition, chiroptical detection raises the detection limits substantially for mixed chiral samples when full separation is not possible.

In comparison, VCD is a simple and nondestructive method for assaying enantiomeric purity. There is no need to physically separate the enantiomers as is required for chiral chromatography, nor are any foreign additives needed such as chiral shift reagents. According to Beer's law, VCD intensities of a single enantiomer are linearly concentration related. As the VCD bands of both enantiomers are but mirror images, they have the same peak positions and intensity but opposite sign. When both enantiomers are present in a mixture, the VCD band intensities decrease in direct proportion with the relative concentration of each enantiomer. Thus, ee assays can be performed when an appropriate calibration plot using single enantiomers is created previously. The availability of multiple transitions in VCD spectra ensures more accurate calibration than the use of a single chromophore band. Because of lower signal-to-noise ratio, the accuracy of the method is limited to about 1% ee obtained to date. Further improvement of accuracy can be expected after development of appropriate chemometric software. The applicability of VCD for determining ee is illustrated for (+)-α-pinene in Fig. 5 (19) and represents the overlaid plot of 11 VCD spectra of (+)-α-pinene with the ee percentage ranging between 100% and 0% in 11 steps. The relationship between the real and predicted ee values is plotted linearly in Fig. 6 (19). Partial least squares (PLS) have been used to account for the entire array of points across the spectrum. This approach results in better correlation between the actual and predicted ee values.

The capabilities of VCD and optical rotation for determining enantiomeric purity were also discussed by Zhao and Polavarapu (20). The advantages of VCD

***FIGURE 5*** *Superposition of the VCD spectra of 11 samples of (+)-α-pinene in the mid-IR region (19)* (copyright PharmaPress Ltd.).

are indisputable when chiral mixtures are to be studied because the individual components can be monitored separately. Further advance in VCD for determining % ee was achieved by constructing a flow cell sampling accessory (21) with which one can monitor simultaneously and with time any changes in fractional composition of a mixture of two different chiral molecules. The VCD set of data was processed by the PLS plus/IQ module in Grams/32 AI (6.0) (Galactic Industries Inc., Salem, NH) because it makes it possible to apply the partial least squares chemometric analysis to determine the percentage ee from VCD spectral data. The proposed sampling accessory can be applied to either single species or a chiral mixture. The accuracy of % ee determination is about 1% for single species and about 2% when two components in a mixture have to be monitored simultaneously (21).

***FIGURE 6*** *Linear plot of prepared VCD % ee versus predicted VCD % ee value (19)* (copyright PharmaPress Ltd.).

## 3.2 Absolute Configuration

The three-dimensional arrangement of atoms around the chiral center of a molecule is known as absolute configuration. Direct access to determine absolute configuration can be assured only by Bijvoet analysis of single-crystal X-ray diffraction or chiroptical methods such as ECD and VCD. X-ray analysis requires a single crystal of a compound of sufficient size and the presence of a "heavy" atom beyond the first row, such as S or Cl. The atom absorbs X-rays to an appreciable extent so that a phase change occurs for the X-ray that is scattered by that atom relative to the other atoms in the structure. This anomalous scattering causes different intensities of reflection that, compared to the calculated intensities for the accepted model, indicate whether the model represents the correct configuration.

NMR spectroscopy is an alternative method for assaying absolute configuration in solution (22). Useful as the method may be in many instances, it is limited for cases in which derivatizing substrates with a chiral substitute are needed and known configurations are required (22). Determining directly the absolute configuration of underivatized chiral compounds is still a challenge. Some progress has been made by using NMR shift reagents; however, these combine the coordination ability of lanthanide ions with their paramagnetic properties (23). In general, routine applicability still remains elusive because finding suitable shift reagents can be difficult.

Other chiroptical methods, such as electronic CD and quite recently optical rotation, could also serve in principle as direct means for determining absolute configuration. For electronic CD, these assessments are based either on one or on a few bands available in the spectral range of interest. The theoretical interpretation depends on the development of computational quantum mechanical methods for both the ground and the excited electronic states. Recent developments of *ab initio* time-dependent density functional theory (TDDFT) for calculating optical rotation in absorption-free spectral regions of chiral molecules made it possible to use optical rotation measurements alone or in combination with other chiroptical methods for determining absolute configurations (24,25).

The other method capable of solving absolute configurations in solution and that requires no prior knowledge for a precursory structure is VCD. It is based on comparing experimental VCD spectra with those computed theoretically either by *ab initio* means or by the more frequently used DFT methods. The theoretical spectrum is generated based on a definitive spatial arrangement of the atoms around the chiral center and an assumed conformation. When an agreement between the band signs of the theoretical and the experimental VCD spectra is reached, the absolute configuration chosen as an input for the calculations is the same as that of the sample. An opposite sign of a calculated band compared to that determined experimentally testifies unambiguously that the opposite enantiomer was selected for calculation. Without calculations, experimentally measured VCD spectra can predict empirically the absolute configuration of chiral molecules provided reference to a structure close to a known absolute configuration exists or a correlation between VCD sign and absolute configuration obeys established chiral rules. Some limitations currently exist. They are imposed either by the VCD experiment or by theoretical treatment.

Sample molecules must show measurable VCD spectra with satisfactory signal-to-noise ratio. Molecules must be reasonably soluble in the usual spectral solvents and show distinct VCD bands. The rigidity of the molecular skeleton, which reduces the number of conformations, usually contributes to intense VCD bands. Conversely, higher molecular flexibility resulting from multiple conformations often leads to weak VCD and poor signal-to-noise ratio. Conformations may also raise the complexity of calculations since every single conformation, which contributes to the overall conformational equilibrium, must be accounted for. The main limitation related to the computations is usually the size of the targeted molecule. Since most computations today are performed on personal computers, there is a practical limit of up to 30 heavy atoms such as carbon, nitrogen, and oxygen. As already mentioned, another reason is the existence of an equilibrium among evenly populated multiple conformations. A relatively small number of conformations could be easily handled, but multiple conformation equilibria effectively increase CPU time. These limitations, however, become less important as the power of personal computers increases.

Solving molecular stereochemistry is straightforward when a chiral structure has a single predominant conformation. For instance, the absolute configuration of 1-azabicyclo[3.1.0]hexane, which is the principal structural fragment of the antitumor antibiotics azinomycins A and B, has been determined by VCD spectroscopy (26). This bridgehead molecule has two chiral centers in its aziridine ring. Geometry optimization and VCD calculations were carried out using RHF/6-31G*(0.3), Becke3LYP/6-31G*, and MP2/6-31G* methods. The optimization by each of these methods yielded only the boat conformation (Fig. 7). The experimental and simulated IR and VCD spectra in the 1500–800 $cm^{-1}$ range are displayed in Fig. 8.

The level of agreement among virtually all VCD bands is very high. There is but one obvious discrepancy observed for the band at 1240 $cm^{-1}$ for which only RHF/6-31G*(0.3) predicted the correct sign. The band cluster at 1300–1150 $cm^{-1}$ is a readily observable signature of unambiguously identifiable enantiomers. The predictions of the three theoretical methods agree well with the experimental features yielding a definitive assignment of the absolute configuration (1*R*,5*S*)-(–)-1-azabicyclo[3.1.0] hexane.

## 3.3 Solution Conformations

Both IR and VCD spectroscopy originate from $3N - 6$ independent vibrations of the molecule, where the frequencies of the molecular transitions range between $10^{12}$ and $10^{14}$ Hz. The timescale of vibrational transitions makes it possible to resolve molecular motions reaching femtosecond limits. This rapid spectral response makes both IR and VCD spectroscopy incisive tools for studying molecular conformations in solution.

The experimental VCD spectrum represents the conformational equilibrium under the conditions chosen for the experiment. When multiple conformations exist, each conformer contributes to the VCD spectrum in accordance with its percentage population. In this case, a conformational search must be performed first leading to structures, relative free energies, and equilibrium populations of the conformers. The theoretical treatment requires that a separate calculation for every single

***FIGURE 7*** *Optimized structure of (1S,5R)-azabicyclo[3.1.0]hexane (26).*

conformer be carried out. Then, the simulated VCD spectrum can be constructed by summing the contributions of the separate conformers weighted by the fractional populations to yield the conformationally averaged composite spectrum. A close match of the experimental and the simulated spectra yields not only the absolute configuration but also the distribution of the solution-phase conformation.

As an illustration, it is useful to demonstrate how (+)- and (−)-enantiomers of *cis*, *cis*-spiro[4,4]-nonane-1,6-diol can be identified as 1*S*,5*S*,6*S*-(+) and 1*R*,5*R*,6*R*-(−), and how their conformation distribution is determined (27). The VCD spectra were obtained with a Bomem MB100 interferometer equipped with VCD optics and described in detail elsewhere (18). The *ab initio* calculations were carried out at the SCF-RHF/6-31G*(0.3) level using the *Gaussian 90* program package. The conformational analysis disclosed six conformers with close energies differing in the ring conformations and the orientation of the hydroxyl groups. The first two conformers separated by 0.3 kJ/mol constituted 86% of the whole population. They were identified to differ in ring conformations and were seemingly intramolecularly hydrogen bonded. The next two conformers with about 5 kJ/mol greater energy contributed another 7% and the last two highest energy conformers displaced by 3 kJ/mol gave the remaining 7% of the conformation distribution. The simulated VCD spectra generated with vibronic coupling theory at the distributed origin gauge are presented in Fig. 9. The first two spectra (a and b) represent the first two conformers of

***FIGURE 8*** *Experimental (a, e) and theoretical (b–d, f–h) IR (a–d) and VCD (e–h) spectra of (1R,5S)-1-azabicyclo[3.1.0]hexane: (f) geometry, force field, and atomic polar tensors at Becke3LYP level and atomic axial tensors at SCF level; (g) geometry, force field, atomic polar tensors, and atomic axial tensors at MP2 level; (h) geometry, force field, atomic polar tensors, and atomic axial tensors at SCF level (26).*

***FIGURE 9*** *Calculated VCD spectra of (−)-(1R,5R,6R)-spiro[4,4]nonane-1,6-diol: 6-31G*(0.3) geometry, force field, atomic polar tensors, and 6-31G atomic axial tensors (a–c). Experimental VCD spectra of both enantiomers: (d) (−)-isomer,* $[\alpha]_D^{22} = -101.4$*, 100% ee; (e) (+)-isomer,* $[\alpha]_D^{22} = +97.1$*, 100% ee (27).*

(−)-(1*R*,5*R*,6*R*)-spiro[4,4]nonane-1,6-diol, whereas the next simulated VCD spectrum (c) is a composite of the six conformers. These are compared with the experimental VCD spectra of the two enantiomers presented in the same figure (d and e). The most intense and characteristic band combination is located between 1150 and 1000 $cm^{-1}$ and appears as negative–positive and positive–negative combinations of bands unambiguously associated with the (−)-enantiomer. The theoretical composite spectrum closely matches the experimental VCD spectrum in almost all features suggesting a close relationship between the actual and assumed conformation distribution. Unlike the absorption where hydrogen bonding complicates the spectrum to such an extent that it seems poorly reproduced, hydrogen bonding in VCD seems not to interfere with these identifications.

For cyclic molecules for which free rotation around simple bonds cannot occur and only a limited number of dihedral angles for internal rotation are available, the most dependable way to find the conformation distribution is to perform potential energy surface (PES) scans by the DFT-PES method. Further optimization of the lowest energy conformers leads to the equilibrium structures of these conformations. This approach was demonstrated by Devlin et al. on a series of the chiral cyclic sulfoxides including 1-thiochroman-4-one *S*-oxide, 1-thiaindan *S*-oxide, and 1-thiochroman *S*-oxide (28). Nearly perfect agreement of the predicted and the experimental spectra was obtained leading to unequivocal assignments of the absolute configurations of these molecules.

The DFT-PES calculation is ineffective for molecules that possess extra flexibility. Finding the distribution of their conformation requires another approach. It is usually carried out in two steps. First, a conformational search using a molecular mechanics force field finds the lowest energy conformers. Their geometries are further optimized by DFT and the VCD spectrum of each conformer is computed. The conformationally averaged VCD spectrum is then compared with the experimental one to provide the assignment of the absolute configuration. The application of this approach is exemplified by solving the absolute configuration of an oxadiazol-3-one *calcium channel blocker* (29). The authors took advantage of a relatively new theoretical development for which the results relied on the simultaneous use of vibrational circular dichroism, electronic circular dichroism, and optical rotation.

The foregoing examples already demonstrate the predictive power of VCD spectroscopy in conjunction with *ab initio* calculations, and more recently in connection with other chiroptical mechanisms. The comparison of the observed and calculated spectra is an effective means for determining the absolute stereochemistry and the conformational distribution. The close agreement of experiment and theory is gratifying and confirms that VCD is a reliable tool for stereochemical analyses.

## 3.4 Pharmaceutical Molecules

The determination of absolute stereochemistry of pharmaceutical molecules is central for their use as drugs given the different biological activities of opposite stereoisomers. The increasing demand posed by the growing interest of pharmaceutical industry requires stereochemical characterizations of relatively large molecules

whereas the level of theoretical models and computational capabilities still remain reasonably modest, although considerable progress is evident. However, and as noted in the preceding section, a different approach emerged in which the interpretation of VCD spectra is based on calculating single fragments of chiral molecules. Since the achiral portion of the molecule in general does not contribute significantly to VCD intensities, it does practically not interfere in particular spectral ranges, such as C–H stretching region for instance. As an example, this approach has been tested on a number of antiarrhythmic and anti-inflammatory drugs depicted in Fig. 10 (30). Diverse VCD markers were established for the molecules studied, which included NH and OH vibrations for free and intramolecularly bonded structures. The appropriate choice of the molecular models allowed the authors to find the most abundant conformers, determine the conformational distribution, and solve the absolute configuration.

***FIGURE 10*** *Molecular structure of antiarrhythmic, anti-inflammatory, and Ephedra drugs (30)* (copyright Marcel Dekker, Inc.).

***FIGURE 11*** *Structures of (M)- and (P)-gossypol (5)* (copyright Wiley-Liss, Inc.).

Historically, it is interesting to note that an absolute configuration was determined of a plant product known as gossypol (5). This compound is a polyphenolic binaphthyl dialdehyde (Fig. 11) for which the hindered rotation around the binaphthyl bond results in axial chirality and consequently in helical arrangement of different handedness M or P. Gossypol itself has attracted considerable interest because, besides its contraceptive activity for males (31), it was also tested as an agent against different human malignancies (32). The absolute configurations of gossypol enantiomers were first established by Huang et al. using electronic circular dichroism when assigning the M configuration to the (−)-enantiomer (33). From among many and varied investigations, one learns that (−)-gossypol's chirality can overcome resistance to apoptosis and may therefore turn out to be a "promising new agent to treat malignancies that are resistant to conventional therapies" (34).

Freedman et al. achieved the first definitive assignment for gossypol by calculating optimized geometries, force fields, and infrared and VCD intensities using *Gaussian 98* at the DFT/B3LYP level and 6-31G* basis set (Fig. 12) (5). Although the binaphthyl skeleton is rather rigid, a molecule can evidently adopt several conformations including different intramolecular hydrogen bonding and various orientations of the aldehyde and isopropyl groups. A conformational search discriminated among three lowest energy conformations that exist at one and the same type of intramolecular hydrogen bonding and differ in relative orientations of the isopropyl group. While the single conformers were separated by about 1 kcal/mol from each other, the relative population was found to be 70:28:2 in favor of the most stable conformer. Precise geometry optimization established a value of 79.1° for the dihedral angle between the naphthalene rings. The conformationally averaged infrared and VCD spectra of (+)- and (−)-gossypol were constructed by assuming Boltzmann distribution of the separate populations together with the experimental spectra. The very close agreement between virtually all spectral features testifies that the P configuration previously assumed for computation can be associated unambiguously with (+)-gossypol. Therefore, it is *the* physiologically active substance and will have M configuration as suggested 20 years ago by applying coupled oscillator theory to its CD (33). This seminal example further demonstrates the appreciable potential of VCD for assigning absolute configurations of relatively large molecules. Without doubt, the combination of VCD with DFT calculations turned out to be eminently capable of predicting the hydrogen bonding pattern and conformation distribution in solution (5).

Although X-ray crystallography has been remarkably useful for resolving absolute configurations, VCD has also become an indispensable method for stereochemical analysis providing additional information when liquid materials are involved. For

***FIGURE 12*** *Infrared and vibrational circular dichroism spectra of gossypol (5)* (copyright Wiley-Liss, Inc.).

example, when attempting to identify new nonpeptide vasopressin receptor antagonists and after the X-ray methods failed, the absolute configuration of a key physiologically active chiral component, such as benzodiazepine, was determined by VCD spectroscopy (Fig. 13) (35). Infrared absorption and VCD spectra were recorded in $CDCl_3$ in the spectral range 1700–800 $cm^{-1}$ on a Chiral*IR* instrument (ABB Bomem/BioTools). Theoretical calculations were carried out at the DFT B3LYP/6-31G* level using *Gaussian 98*. Three distinct conformers were identified by geometry optimization differing in the conformations of the six- and seven-membered rings. Separate calculations of absorption and VCD intensities of every

***FIGURE 13*** *Structure of (+)-chiral benzodiazepine (35)* (copyright Wiley-Liss, Inc.).

single conformer have been necessary in order to associate the observed VCD spectrum of the (+)-enantiomer with the true absolute *S* configuration of the asymmetric carbon (35).

Full agreement was achieved for (+)-McN-5652-X in the absolute configuration between prior single-crystal X-ray diffraction and recent VCD measurements (36). This compound belongs to a novel series of pyrrolo[2,1-*a*]isoquinolines considered to be selective inhibitors of serotonin reuptake *in vivo* and therefore possessing potential antidepressant activity. The single-crystal X-ray diffraction of (+)-McN-5652-X salts with $HClO_4$ and (+)-(2*R*,3*R*)-tartaric acid provided evidence for the (6*S*,10b*R*) absolute configuration and relative *trans* configuration between $C_6$ and $C_{10b}$ (Fig. 14). A VCD study in $CDCl_3$ confirmed the previous X-ray crystallographic assignment and identified the highest populated solution conformation as a transfused 5,6 ring junction in which the nitrogen configuration is *R* (36).

Dunmire et al. examined the VCD spectra of ketoconazole, itraconazole, and miconazole, three chiral drugs that are used as antifungal agents (37). These VCD studies confirmed the previous assignment of the absolute configurations, which were inferred solely on the basis of syntheses. In order to avoid DFT calculations of (+)-ketoconazole and (+)-itraconazole, which would have been necessary for

*trans*-(6*S*, 10b*R*)

***FIGURE 14*** *Structure of (+)-McN-5652-X (36)* (copyright Elsevier Science Ltd.).

***FIGURE 15*** *Structures of (2R,4S)-ketoconazole, (2R,4S)-itraconazole, and (S)-miconazole and fragments 1 and 2 used for calculations (37)* (copyright Wiley-Liss, Inc.).

identifying solution conformations and establishing the absolute configurations, a fragment common for the two molecules was used (Fig. 15). This fragment contains two chiral centers, which should have been sufficient for identifying features to compare with the VCD experiment. The contribution of the third chiral center of (+)-itraconazole was accounted for by calculating the second fragment. The VCD spectrum of (*S*)-miconazole was simulated by computing the geometry, force field, and VCD intensity of the whole molecule and its protonated form. By comparing the composite spectra constructed from the most abundant conformation populations and the experimental VCD spectra, the absolute configuration was confirmed for (+)-(2*R*,4*S*)-ketoconazole, (+)-(2*R*,4*S*)-itraconazole, and (+)-(*S*)-miconazole.

Most of the chiral molecules studied conveniently have isolated vibrational modes in the VCD spectrum in which the chiral center is involved. In some instances, these modes are either hidden in the fingerprint region or obscured by solvent absorption rendering them unsuitable for stereochemical assignments. To determine by VCD the absolute configuration of the cruciferous phytoalexin metabolites (−)-dioxybrassinin and (−)-3-cyanomethyl-3-hydroxyoxindole, Monde et al. had to use DMSO-$d_6$,

***FIGURE 16*** *Structures of cruciferous phytoalexin-related metabolites (−)-dioxybrassinin and (−)-3-cyanomethyl-3-hydroxyoxindole (38)* (copyright Elsevier Ltd.).

which required a very thin (6 μm) $CaF_2$ cell, thereby substantially reducing the VCD window. Only a few characteristic bands located at 1730, 1620, and 1470 $cm^{-1}$ were available of which the first two were readily assigned to C=O stretch and aromatic ring stretch. As indicated earlier, this *concerted* mechanism combined the calculations for VCD with ECD followed by optical rotation (38). In this manner, the absolute configurations of (−)-dioxybrassinin and (−)-3-cyanomethyl-3-hydroxyoxindole were unequivocally determined. This was the first attempt to determine absolute configurations of tertiary alcohols by VCD. The approach could well be generalized for other stereochemical assignments of tertiary alcohols (Fig. 16). Noteworthy in this particular case was that their absolute configurations were determined by involving vibrational CD together with the more conventional electronic CD.

Earlier in the foregoing text, oxadiazol-3-one was referred to as a "calcium channel blocker" (29). This designation was originally proposed by B.J. Materson in 1995 to avoid confusing designations with related drugs (39). Since then, a variety of calcium channel blockers were scrutinized in order to test a series of substances, explicitly [1,4]thiazino[3,4-*c*][1,2,4]oxadiazol-1-one derivatives (40) and a new class of calcium channel modulators (41). In a more recent publication, these authors speak of a multidisciplinary project that "has led to the discovery of novel, structurally diverse, L-type calcium entry blockers (CEBs)." The absolute configuration of a recently reported CEB has been determined by vibrational circular dichroism spectroscopy to assign the stereospecificity of the ligand–channel interaction (42). From a "purchasable" database, they screened 340,000 molecules and tested 20 compounds *in vitro* obtaining several potentially promising calcium entry blockers. As mentioned earlier, the absolute configuration of the related compound 8-(4-Br-phenyl)-8-ethoxy-5-methyl-8*H*-[1,4]thiazino[3,4-*c*][1,2,4]oxadiazol-3-one (Fig. 17) (29) also possesses the proven activity of a calcium channel blocker as determined with VCD, ECD, optical rotation, and accompanying DFT calculations. Oxadiazol-3-one is rather flexible with multiple conformations arising from the nonplanar thiazino ring as well as from free rotations of the ethoxy and phenyl groups. A conformational search by MMFF94 force field detected a large number of conformations, which when reoptimized by B3LYP/6-31G* led to 13 stable conformers within 8 kcal/mol. More accurate DFT calculations using the larger basis set TZ2P rejected most of the conformations but kept the three lowest energy conformers a, b, and c (Fig. 18). The

***FIGURE 17*** *Structure of 8-(4-Br-phenyl)-8-ethoxy-5-methyl-8H-[1,4]thiazino[3,4-c][1,2,4]oxadiazol-3-one (29)* (copyright American Chemical Society).

conformers a and b are separated by only 0.78 kcal/mol but consist of 97.5% of the whole population at room temperature. Conformer a alone consists of more than 80%. The very thorough analysis of VCD spectra of the oxadiazol-3-one established definitively that the absolute configuration of the (+)-enantiomer is *S*, and the (−)-enantiomer having higher physiological activity has *R* configuration (29).

## 3.5 Natural Products

The absolute stereochemistry of a series of natural products was investigated extensively by the group of Philip Stephens who reported the "first concerted application of density functional theory calculations," which included VCD, ECD,

***FIGURE 18*** *B3LYP/6-31G* structures of conformations a, b, and c of (S)-oxadiazol-3-one (29)* (copyright American Chemical Society).

***FIGURE 19*** *Structures and absolute configurations of the schizozygane alkaloid schizozygine (43) and the isoschizozygane alkaloids isoschizogaline and isoschizogamine (44)* (copyright American Chemical Society).

and optical rotation spectra. Among the compounds, they first investigated the schizozygane alkaloid schizozygine (43) and the isoschizozygane alkaloids isoschizogaline and isoschizogamine (Fig. 19) (44). All three of these alkaloids were isolated from *Schizozygia caffaeoides*, a plant traditionally used in Kenyan folk medicine. Although the structures of these alkaloids were determined by NMR, their absolute configurations were still unclear until very recently. By combining chiroptical methods and high-level DFT calculations, Stephens et al. were able to assign unambiguously the absolute configurations of the alkaloid (+)-schizozygine, which has (2*R*,7*S*,20*S*,21*S*) configuration (43), as do both (−)-isoschizogaline and (−)-isoschizogamine, which have one and the same configuration, namely, (2*R*,7*R*,20*S*,21*S*) (44).

Equally compelling are the assignments for plumericin and isoplumericin iridoids. Plumericin and its isomer isoplumericin, first isolated from *Plumeria multiflora* and *Plumeria rubra* var. *alba*, were found to have antifungal and antibacterial activity. The structures were established originally by Albers-Schönberg and Schmid in 1961 (45), although some doubt remained whether these assignments were correct. Consequently, a comprehensive study of the above-mentioned iridoids was performed very recently bringing to bear VCD, commensurate density functional calculations, electronic CD and optical rotation (46) (Fig. 20). A conformational search revealed four stable conformations within $\Delta E = 2$ kcal/mol. The refined geometry of the lowest

***FIGURE 20*** *Structures of plumericin and its isomer isoplumericin (46)* (copyright American Chemical Society).

energy conformers at the B3PW91/TZ2P level of theory led to conformationally averaged infrared and VCD spectra, which were found to be equivalent to those observed. It was therefore concluded definitively that the absolute configuration of both (+)-plumericin and (+)-isoplumericin is (1*R*,5*S*,8*S*,9*S*,10*S*), confirming the previous assignments of Albers-Schönberg and Schmid (45). Two years earlier, a different absolute configuration was proposed (45) suggesting that the absolute configuration of plumericin and isoplumericin should be (1*S*,5*R*,8*R*,9*R*,10*R*), that is, the reverse of that identified by density functional theory and experimental spectroscopic evidence. Stephens et al. (44) evidently provided the correct interpretation and also demonstrated that the method is more reliable based partially on the combination of VCD, TDDFT, electronic CD, and optical rotation (46).

The structure of a *new* and highly cytotoxic iridoid, isolated from prismatomerin (*Prismatomeris tetrandra*), was found in which a methyl group is substituted by a *para*-phenol group (Fig. 21) (47) and was very similar to the previously studied plumericin. In order to avoid intermolecular hydrogen bonding, the absolute configuration of prismatomerin was inferred from its acetate derivative, which has the same absolute configuration. Based on the VCD spectra in $CDCl_3$ and B3PW91/TZ2P calculations, it was concluded that the naturally occurring (−)-prismatomerin has (1*R*,5*S*,8*S*,9*S*,10*S*) configuration (47,48), identical to that of (+)-plumericin (46) even though it has positive $[\alpha]_D$.

Other natural products with closely related chemical structures and nearly equal $[\alpha]_D$ revealed that they have opposite absolute configurations. For example, the iridoid oruwacin, isolated from *Morinda lucida*, was identified by NMR to have a structure very close to that of plumericin (49). The $[\alpha]_D$ values measured in $CHCl_3$ are +193 for oruwacin and +197 for plumericin. Seemingly, the replacement of the methyl group at $C_{14}$ by a phenyl ring bearing $OCH_3$ and OH groups had not affected the

(–)-(1*R*, 5*S*, 8*S*, 9*S*, 10*S*)

***FIGURE 21*** *Structure of prismatomerin (47,48).*

***FIGURE 22*** *Structures of (+)-oruwacin and (+)-plumericin (50)* (copyright American Chemical Society and American Society of Pharmacognosy).

optical rotation. On this basis, it was concluded that both (+)-enantiomers have (1*R*,5*S*,8*S*,9*S*,10*S*) configuration.

However, the calculation of the optical rotation for the two enantiomers of oruwacin using TDDFT has shown that the absolute configuration (1*R*,5*S*,8*S*,9*S*,10*S*) has $[\alpha]_D$ −193, while (1*S*,5*R*,8*R*,9*R*,10*R*) has + 193 (Fig. 22) (50). This result clearly demonstrates that assignments of absolute configurations solely made on the basis of closely related structures and almost equal $[\alpha]_D$ may be erratic.

## 4 METAL IONS, DRUGS, AND PROTEINS

It is well known that DNA and RNA structures respond to interactions with metal ions, drugs, and proteins. Examples of these are selected and articulated below to demonstrate the variety of outcomes of some investigations documented in the available scientific literature.

### 4.1 Metal Ions

Metal ions have distinctive functions in biological systems where they participate in a number of biological processes. Being a major component in life's systems either for the benefit or to the detriment of physical health, one can hardly ignore the need to better understand details of why and how vibrational circular dichroism is able to assist in determining the role it can bring to bear on attempting to ensure *quality of pharmaceutical products*. A realization of the involvement of metal ions in nucleic acids (51,52) followed only a few years after the discoveries of Watson and Crick. The first particularly extensive and comprehensive publication appeared in 1976 (53). Of further interest are several publications that deal with metal ions interacting with

nucleotides, nucleic acids, and their constituents (54–60). By the same token, it is also important to be aware of less desirable aspects of metal ions particularly for human life cycles (61–64).

Compared to conventional infrared absorption spectroscopy as applied to interactions of DNA (or oligomers) with metal ions (65–68), relatively few applications of VCD spectroscopy on these topics can be found in the literature. Considering that VCD signals are generally less intense than those of absorption, simpler oligonucleotides rather than whole DNA have originally provided the desired insights. In one specific case, VCD measurements were used to examine the interaction of $Mn^{2+}$ with $d(GC)_{20}$ and $d(ATGCATGCAT)_2$ (69). The VCD and absorption spectra of the two duplexes were compared without $Mn^{2+}$, with 0.64 [Mn]/[P], and with 0.50 [Mn]/[P]. Essentially no differences in absorption were apparent with only a minor change in VCD in the phosphate region. However, more substantive differences emerged when the spectra of the two oligomers were compared *without* and *with* the manganese ions. The appreciably different spectra suggested unambiguously that VCD provides better definition of structural changes in helical conformations (69).

A theoretical interpretation of the B–Z transition was particularly informative (4). The self-complimentary $d(GC)_{20}$ duplex was measured in the B- and Z-forms and compared to that observed, as well as computed B-conformation without and with explicit water molecules. The results of these aspects are at least twofold: first, the confirmation of the experimental observations with respect to the B–Z transition (69), and second, the computational results that correspond to the observed spectra. The absorption and VCD spectra for the two conformations are portrayed not only in the nitrogen base region but also in the phosphate regions.

The foregoing text dealt mainly with DNA *oligomers* and the interaction with metal ions, specifically $Mn^{2+}$ as a test case. The principal importance of this example is the extent to which VCD can provide structural information in this context (70). The metal concentration was varied from 0 to 0.73 M $Mn^{2+}$ (0–8.5 moles of $Mn^{2+}$) per mole of oligonucleotide phosphate, [Mn]/[P]. In general, the spectra displayed considerable changes as the $Mn^{2+}$ concentrations were increased and the differences were frequently complementary in expression and extent. The main phase of the transition occurred between 0.8 and 1.1 [Mn]/[P]. The spectra transformed gradually in terms of the B–Z transformation binding $Mn^{2+}$ to phosphates and the nitrogen bases as well as partial denaturation. Below 0.6 [Mn]/[P], only a small portion of the oligonucleotide adopted the Z conformation within 3 h; conversion was completed in the same time interval for concentrations between 0.9 and 1.2 [Mn]/[P].

Whereas the absorption spectrum does not change significantly upon the addition of $Cr^{3+}$, changes in the intensity of certain VCD peaks (either positive or negative) are very distinct (Fig. 23) (71). There is no evidence of DNA denaturation even at the highest $Cr^{3+}$ concentration, which was one of the principal purposes for this particular exercise. The main differences between 1750 and 1600 $cm^{-1}$ upon metal ion binding are connected to N7 of guanine. When the $Cr^{3+}$ concentration is raised to 0.6 [Cr]/[P] (DNA + 0.06 M $Cr^{3+}$), the VCD amplitudes increase considerably at several wavenumber positions. At higher concentration, for example, 3 [Cr]/[P], the VCD and absorption features are again similar to those at the start. Within existing

***FIGURE 23*** *Absorption and VCD spectra of DNA with $Cr^{3+}$: (a) DNA + 0, 0.6, 1, 2, and 3 [Cr]/[P]; (b) DNA + 0.6 [Cr]/[P], solid and dotted contours correspond to spectra taken 100 and 220 min after preparing the sample; (c) DNA + 3 [Cr]/[P], 220 min after preparing the sample.*

theory (72,73), the greatly increased amplitudes are referred to as "ψ-type" spectra. Cheng and Mohr (74) referred to this phenomenon as causing DNA to "collapse into rapidly sedimenting form"; Shin and Eichhorn (75) spoke of "structural polymorphism of DNA involved in determining its biological activities"; and Kim et al. (76), who developed the theory of "interaction of light with large inhomogeneous molecular aggregates," referred to it as "psi-type circular dichroism," which is the currently accepted chemical term. In this context, VCD can detect DNA condensation as "particles" of a size comparable to the wavelength of the probing light; in other words and together with suitable metal ions, it can tell something about DNA packing in a living cell. The principal motivation for including trivalent chromium $Cr^{3+}$ ion into this discussion was to demonstrate the capacity and versatility of VCD for detecting DNA *condensation*. The phenomenon itself is well understood and has been known for some time. But it was an important question whether VCD spectroscopy would join the investigative biophysical arsenal (69–76).

The literature that deals with complexes of $Cu^{2+}$ with DNA and oligomers is rather captivating and extensive. Many of the publications dating back to 1966 are captured in a recent treatment dealing explicitly with VCD in combination with infrared absorption spectroscopy (77). In order to be able to distinguish the changing shape of the spectra upon increasing the amount of [Cu]/[P], the solid lines delineate DNA with progressively increasing amounts of [Cu]/[P], whereas the dotted lines represent DNA together with preceding amounts of [Cu]/[P] (Fig. 24). The first addition of $Cu^{2+}$ ions ([Cu]/[P] = 0.2) led only to very minor changes in the DNA spectrum. For subsequently increasing quantities of [Cu]/[P], that is, 0.4, 0.5, and 0.7, each spectrum was compared to that of the previous combination. The most prominent changes are those that occurred for DNA + 0.5 [Cu]/[P] and DNA + 0.7 [Cu]/[P]. Although interpretation is a challenging task, the emerging details with regard to the effects of $Cu^{2+}$ ions on VCD spectra are unmistakable. For example, a barely detectable VCD peak at 1642(+)/1617(−) $cm^{-1}$ for DNA itself emerges as a distinct feature already with 0.2 [Cu]/[P] and thereafter develops as a prominent VCD couplet

***FIGURE 24*** *Absorption (bottom) and VCD (top) spectra of calf thymus DNA with [Cu]/[P]: 0.4 (a), 0.5 (b), and 0.7 (c).*

at 1636(+)/1619(−) cm$^{-1}$ for DNA + 0.4 [Cu]/[P] and at 1637(+)/1616(−) cm$^{-1}$ for DNA + 0.5 [Cu]/[P] (Fig. 24a and b), but becomes indistinguishable for DNA + 0.7 [Cu]/[P] (Fig. 24c). Prominent also are the VCD signals in the sugar–phosphate region. Emerging details via VCD suggest that little if any significant distortion of Watson–Crick hydrogen bonding or denaturation occurs at 0.2 [Cu]/[P]; distinct changes in VCD indicate $Cu^{2+}$ binding to N7 of guanine, but $Cu^{2+}$ does not interact with $O_2$ of thymine; rather, $Cu^{2+}$ interacts with N3 of cytosine. No significant DNA denaturation is evident. Base stacking is reduced appreciably above 0.4 [Cu]/[P]. The sugar–phosphate backbone remains highly ordered. Finally, the VCD spectrum at 0.7 [Cu]/[P], which has undergone major changes, indicates denaturation of DNA, although quite weak couplets in the sugar–phosphate region signal a partially ordered structure. As one final observation, it is of interest to emphasize that in this case the VCD spectra enabled a cogent summary of why $Cu^{2+}$ ions behave differently with DNA from other metal ions.

If $Mn^{2+}$ ions can induce *condensation* in DNA, either at room temperature or at elevated temperature, can it also lead to *aggregation*? For clarity, the word *condensation* is defined as "formation of dense and relatively large particles in which DNA molecules are packed with a regular arrangement," whereas *aggregation* is understood as "a significantly decreasing volume occupied by the DNA molecule forming large but relatively loose molecular aggregates with an unordered arrangement" (78). The particles of the former are capable of creating ψ-type spectra, whereas those of the latter associate in unordered arrangements. Keeping in mind that theoretically as well as experimentally condensation and aggregation have long been understood, the principal objective of this investigation was to determine whether VCD would be able to determine the presence or absence of DNA condensation and aggregation and also distinguish between these two phenomena. As the first step, the absorption and VCD spectra were measured for calf thymus DNA at different temperatures. Thereafter, the spectra were obtained for four different sets of [Mn]/[P] ratios and two different temperatures (23 and 55°C).

The set of VCD experiments involving $Mn^{2+}$ ions revealed several insights. The secondary structure remained in the B-form during the whole ion concentration range

at room temperature. No significant denaturation of DNA occurred at room temperature even at the highest metal ion concentration. At elevated temperatures, the manganese ions caused decreasing stability, and melting temperature of DNA accompanied denaturation. Evidently, VCD is sensitive to DNA condensation or aggregation, and by the same token it is also able to distinguish between these processes. Although condensation of DNA became evident in a narrow range of experimental conditions near 2.4 [Mn]/[P] and 55°C, aggregation took place in the presence of $Mn^{2+}$ ions at these elevated temperatures, during or after denaturation.

From a relatively simple experiment by today's standards, Rosenberg, Van Camp, and Krigas provided inadvertently a possibility to combat cancer: "In an investigation of the possible effects of an electric field on growth processes in bacteria, we have discovered a new and interesting effect." (79). Of course, the chemical substance pertaining to this event is cisplatin, as is well known. Much has been learned and published since then about the benefits and shortcomings of this relatively simple material as well as its structure and mode of action. Some attempts have been made to determine what contributions this physical–chemical method could offer from the perspective of vibrational circular dichroism, although the nature of the subject and its tools have so far limited the scope of these endeavors. In two relatively recent publications, the authors have probed the feasibility, accuracy, and practical value of VCD for this purpose. In the case of the octamer d(CCTG*G*TCC)·d(GGACCAGG) (80), the multiple positive and negative peaks in the VCD spectra looked enticingly interesting (Fig. 25). Reasonable wavenumber positions are relatively easy to ascertain particularly for this octamer and without

***FIGURE 25*** *Absorption and VCD spectra of cisplatin–d(CCTG* G* TCC)·d(GGACCAGG) adduct: (a) octamer without cisplatin; (b) octamer with cisplatin.*

cisplatin; what appear to be complicated spectra especially for the cisplatin complex can also be readily assigned (Table 1). Although the VCD spectra may look somewhat confusing, their interpretation too is relatively easy. Notable, for instance, are significant intensity decreases in the VCD spectrum of the platinated octamer (1750–1500 $cm^{-1}$), or specifically a new couplet at 1631(+)/1619(−) $cm^{-1}$, which is not apparent in the unplatinated sample. Upon being exposed to cisplatin, the octamer isomerizes from an *intra*strand to an *inter*strand cross-link as demonstrated in an earlier NMR analysis (81). Figure 24a and b clearly confirms that while the absorption spectra of the complex are less affected, the VCD spectra differ considerably. It is not entirely clear from this particular experiment what structure emerges, but it is clear that the spectra are affected to a considerable extent in both the 1750–1500 and 1100–900 $cm^{-1}$ ranges. Specifically, the fourth base step between G4pG5 is connected to platinum via the N7 atoms of guanine, where most prominent changes occur in the spectra. Whereas absorptions do not change with time, the VCD spectra are progressively altered due to a slow isomerization from *intra*strand to *inter*strand cross-links (80).

The absorption and VCD spectra of the same octamer together with cisplatin were modeled by *ab initio* simulation using density functional computations and a Cartesian coordinate-based transfer of molecular property tensors from smaller DNA fragments (8). If successful in this endeavor, situations are likely to emerge when this combination of theoretical and physical methods will provide compelling support for interpreting VCD spectra alongside infrared absorption and other physical–chemical methods. Although a computed *absorption* spectrum, which used a scaled BPW91/6-31G** force field, might be considered a reasonable reproduction, the VCD spectra leave something yet to be desired.

Compared to the infrared absorption spectrum of d(CCTG*G*TCC)·d(GGACCAGG), its VCD trace appears greatly more interesting and challenging. Although perhaps difficult, the multitude of absorption signals without cisplatin is likely to be readily interpreted, but those of VCD are more difficult from a different perspective (Table 1). The correlation between the spectra of the free and complexed oligomers is truly remarkable, although it can be expected that the spectral details of an entire DNA are likely even more complicated. The strong absorptions stand out clearly, whereas the weaker ones are often only suggestive. In contrast, the VCD spectra reveal a rich variety of signals that are even more prominent in their details especially in the presence of cisplatin.

While informative, the results of cisplatin when complexed with the octamer did not indicate whether spontaneous conversion from an *intra*strand to an *inter*-strand oligomer takes place independent of the chain length. The dodecamer d(CCTCTG*G*TCTCC)·d(GGAGACCAGAGG) (Fig. 26) was therefore complexed with cisplatin and the absorption as well as VCD spectra recorded (Fig. 26a and b, Table 2) (82). Both the absorption and VCD spectra differ appreciably between those of the octamer and dodecamer, but differ more prominently between the free and complexed dodecamer. VCD features of the dodecamer are significantly overlapped particularly in the 1750–1500 $cm^{-1}$ range and then even more upon complexation with cisplatin. Although changes in absorption are also significant, they are not as

prominent as in VCD. Both the absorption and VCD spectra indicate a typical B configuration for the dodecamer and the octamer. Pertinent is also the fact that both the absorption and VCD spectra are changed significantly upon complex formation. Of all the differences that were noted, the most pertinent observation is that the effects of platination on the dodecamer duplex were changes in VCD expressed specifically by the vibrations of the guanines to which the platinum atoms become attached, namely, G*6 and G*7. Further, the spectra did not indicate that any isomerization of the complex had taken place contrary to what was observed for the octamer. The major thrust that emerged from the foregoing text is that VCD is capable of making significant contributions to generating new knowledge about specific drugs perhaps aided in combination with appropriately sophisticated *ab initio* simulations.

## 4.2 From Simple to Greater Challenges

Various aspects of metal ions were considered in Section 4.1. The components include a range of publications all of which focused mainly on interactions of oligomers or DNA with metal ions (69–71,77,78). Examples of infrared absorption and vibrational circular dichroism combining DNA with metal ions *and* proteins are articulated below (80–89). Included are combinations of DNA with $Mn^{2+}$ (69,70,78,83), $Cu^{2+}$ (77), $Pt^{2+}$ (80,82), and the proteins HMGB1 and H1 in addition with DNA forming large supramolecular complexes using UV, infrared absorption, and vibrational circular dichroism (84–88), HMGB1 in the presence of $Mn^{2+}$ using UV and CD (85) and DNA/HMGB1/H1 complex with $Mn^{2+}$ (86). In all these instances, the effects on DNA and the selected proteins in the presence of the metal ions are clearly evident. In another investigation, which used infrared absorption and vibrational circular dichroism as well as electronic circular dichroism spectroscopy, the effect of $Ca^{2+}$ ions on DNA was considered

**TABLE 2 Absorption and VCD Data of d(CCTCTG*G*TCTCC)·d(GGAGACCAGAGG) Free and Complexed with Cisplatin (Fig. 26)**

| Assignment | Dodecamer Free | | Dodecamer–Pt Complex | |
|---|---|---|---|---|
| | Absorption | VCD ($cm^{-1}$) | Absorption | VCD ($cm^{-1}$) |
| C=C base stretching modes | 1727 | 1733(+)/1724(−) | | 1729(+)/1718(−) |

| | 896 | | 896 | |
| | 866 | | 866 | |

leading to compaction when complexed with non-histone HMGB1 (87). Intricate details emerged from the IR/VCD perspective via a study of DNA-$Ca^{2+}$ interaction in the infrared regions from 1750 to 1300 and 1150 to 750 $cm^{-1}$. The molar ratio of $Ca^{2+}$ to DNA phosphate in solution, $R = [Ca^{2+}]/[P]$, ranged from 0.015 to 1.3; the absorption and VCD features resembled very closely those of $Mn^{2+}$ and DNA (70). The regions between 1750 to 1500 and 1150 to 800 $cm^{-1.}$ differed only in lesser nuances. The forerunner to this work was an earlier analysis, which compared the behavior of DNA on interaction with HMGB1 and H1 at different ionic strengths and protein content (88). The applications of IR/VCD spectroscopy to study proteins and their complexes with DNA were described recently elsewhere (89).

## 5 SUMMARY AND CONCLUDING REMARKS

The principal purpose of this article was to provide a relatively brief overview of today's utility of *vibrational circular dichroism*. This article focuses on instrumental methods, unique applicabilities and capabilities, review of scientific applications such as enantiomeric purity and absolute configuration, solution conformations, pharmaceuticals, and natural products, and concludes with an assessment of the instrumentation's utility when metal ions play significant roles in biological and medicinal processes, and the observation that the same metal ions significantly affect large molecular biological complexes that arise from the interactions of DNA, proteins, and medicinal drugs.

Section 2 deals with the principles of vibrational circular dichroism and required instrumentation methods, and thereafter discusses the uniqueness and applicability of results. These components are intended as quick recitals for someone who is not familiar with the instrumentation. In Section 3, one is reminded of several aspects of vibrational circular dichroism spectroscopy. These turn out to be significant, important, and useful. Among them are topics that deal with enantiomeric purity, enantiomeric excess, and absolute configuration. All three of these are generally useful. Conformation of solutions is usually a desirable element, which can assist in identifying details of absolute configuration. The subsection that deals with pharmaceutical molecules focuses on materials of medicinal purpose such as *Ephedra* drugs, gossypol, and oxydiazol-3-one, to mention but a few. The last subsection highlights natural products, usually extracts of various plant materials, such as the family of alkaloids for instance. It is in this subsection that the density functional theory calculations have proven to be very successful.

Finally in Section 4, metal ions in combination with medicinal drugs and proteins demonstrate a functional capability for expressing stereochemical effects on nucleic acid oligomers, whole DNA, and potential drugs of various kinds.

## 1 INTRODUCTION

Solid-state NMR (SSNMR) spectroscopy is a commonly applied analytical technique in pharmaceutical development. Reviews of the pharmaceutical applications of SSNMR have recently appeared (1–4); texts in the field of solid-state pharmaceutical chemistry also include detailed discussions and applications of SSNMR (5–8). This chapter attempts to summarize the current status and latest developments in the field of applied pharmaceutical SSNMR from an industrial perspective, focusing on the utility of the technique during the development of a drug from the candidate stage through to a marketed, approved product. Particular attention is given to the latest approaches to the

use of SSNMR in pharmaceutical analysis, including detailed structural analysis of active pharmaceutical ingredients (APIs) and analysis of formulations.

The solid-state structure of a pharmaceutical product can influence its properties, manufacturability, and stability. Since these characteristics can impact product performance and patient safety, regulatory agencies require control over solid-state structure and subsequent properties (9–11). Solid-state analysis of pharmaceuticals is a challenging field and a number of complementary techniques are frequently needed to understand the complete system. Typically, knowledge of the API polymorphic forms, salts, and solvates, as well as the physical characteristics of excipients, granulations, tablets, parenteral products, and other dosage forms, is built during the drug development process. SSNMR can be a critical part of an integrated analytical strategy for addressing the questions faced in the development process because of its high information content and flexible experimental design (12). Subsequently, analytical methods are developed to enable rapid testing of many batches and ensure control. Although SSNMR methods can be quite sensitive and have many other desirable properties, the complexity and expense associated with current instrumentation often lead to the use of X-ray powder diffraction (XRPD) and the various forms of vibrational spectroscopy when routine analysis is required (12). However, in some cases, SSNMR can be applicable to the testing of a wide range of batches, particularly to detect and understand subtle variations in solid-state structure that are not detected by lower resolution techniques, or when high sensitivity drug product analysis is needed.

SSNMR is closely related to the widely used technique of solution-state NMR and shares many of the same features (13). The theory used to describe SSNMR experiments and their results is identical to that of solution-state NMR, but includes special consideration of three NMR interactions that have particular manifestations in the solid state: the anisotropic chemical shift, magnetic dipolar coupling, and quadrupolar coupling (14,15). Because of these interactions, specialized experimental methods and pulse sequences, such as magic-angle spinning (MAS) and cross-polarization (CP), are widely used and thoroughly permeate any discussion of SSNMR (16).

This chapter reviews the current status of applied pharmaceutical SSNMR, first focusing on the latest innovations in technology and methodology of relevance to pharmaceutical analysis and then providing an overview of the present and future applications of this technology and methodology to API, formulated products, and excipients, illustrated with examples from current practice. SSNMR has advanced considerably in the past decade, with multinuclear and multidimensional experiments now commonly encountered in pharmaceutical applications (17).

## 2 METHODS

### 2.1 Accessible NMR Nuclei in Pharmaceuticals

Experimental methods for SSNMR spectroscopy of pharmaceuticals are closely related to the properties of the nuclei of interest. The isotopes generally used in

pharmaceutical applications are summarized in Table 1. Although the $^{13}C$ isotope is the dominant nucleus used in pharmaceutical applications of SSNMR, other nuclei have begun to play a wider role. Pharmaceutical SSNMR analyses generally rely on the natural abundance of the isotopes given in Table 1. Isotopic spin labeling, although it is predominant in other applications of SSNMR, is not commonly used in pharmaceutical SSNMR analysis. However, spin labeling has been used in certain special applications requiring high sensitivity, for example, to detect the form of an API or an excipient at levels of $<1\%$ w/w (12,18). The pharmaceutical relevance, key NMR properties, and experimental NMR parameters for each nucleus in Table 1 are discussed below; applications of each nucleus to various analytical issues in pharmaceutical development are discussed in Section 3.

***2.1.1 Carbon-13*** Carbon forms the backbone of most pharmaceutical molecules and has reasonable sensitivity and natural abundance. The $^{13}C$ nucleus is well positioned to report on changes in the 3D structure of a drug molecule or excipient, including such effects as conformation, hydrogen bonding, packing interactions, and ionization. As a result, $^{13}C$ is by far the most commonly observed NMR isotope in pharmaceutical SSNMR applications. Extensive literature covering the empirical chemical shift parameters for $^{13}C$ is available from solution-state studies (19). The $^{13}C$ SSNMR spectra of pharmaceutical solids are generally referenced to TMS via an external reference such as glycine or hexamethylbenzene (20) and can serve as the base reference for other nuclei studied by a SSNMR system using ghost referencing (21). The $^{13}C$ chemical shift tensor (CST), which offers information beyond that available from isotropic shifts alone and is discussed in detail below, has also been extensively studied and related to structural trends (22). The $^{13}C$ isotope often shows large, interpretable effects in the principal values of its CST; this is often referred to as strong chemical shift anisotropy (CSA) (22).

***2.1.2 Hydrogen Isotopes*** Hydrogen, the other backbone element of organic pharmaceuticals, contains two isotopes of particular interest in pharmaceutical SSNMR. The $^{1}H$ isotope is a sensitive, highly abundant spin 1/2 nucleus, as shown in Table 1. However, its relatively narrow chemical shift range and ability to engage in strong dipolar coupling cause most $^{1}H$ SSNMR spectra of pharmaceuticals to be broad and featureless unless special methods are used (23). Dipolar coupling arises because of the through-space interaction of the magnetic moments of one nucleus with other nuclei that are spatially proximate (14–16). The magnitude of this interaction between $^{1}H$ nuclei can reach up to 50 kHz and is significantly stronger than the weak and difficult to measure $^{1}H$ CSA. The dipolar interaction provides an avenue to obtain a wealth of structural information when it can be removed and selectively reintroduced by specialized SSNMR experiments (23). Hydrogen also exists as a spin 1 isotope $^{2}H$ (deuterium), a quadrupolar nucleus that can also be used in the study of pharmaceuticals. Although not generally useful in natural abundance, $^{2}H$ exchange in readily available deuterated solvents and reagents can be achieved, so that partial incorporation of deuterium into pharmaceutical solids

**TABLE 1 Properties of Pharmaceutically Relevant NMR Active Nuclei[a]**

| Isotope | Spin ($I$) | Frequency in MHz at 2.344 T | Natural Abundance | Receptivity [b] | Notes |
|---|---|---|---|---|---|
| $^{1}H$ | 1/2 | 100.000 | 99.985% | 1.0000 | Narrow chemical shift range, very sensitive. Historically used infrequently due to large solid-state linewidths, but becoming more prevalent because of higher fields and increased resolution from dipolar decoupling and fast MAS |
| $^{2}H$ | 1 | 15.350 | 0.015% | 0.00000145 | Too insensitive for natural abundance, but introduced through isotope labeling. Can be used to study hydrates and water exchange |
| $^{11}B$ | 3/2 | 32.084 | 80.1% | 0.132 | Useful for characterization of boron-containing pharmaceuticals |
| $^{13}C$ | 1/2 | 25.145 | 1.10% | 0.000170 | The most widely used and informative nucleus for pharmaceutical analysis |
| $^{15}N$ | 1/2 | 10.137 | 0.366% | 0.00000384 | Low abundance, insensitive, and useful for determining ionization state |
| $^{17}O$ | 5/2 | 13.556 | 0.038% | 0.0000111 | Only accessible via isotope labeling. Can be used to assess the role of water in pharmaceutical hydrates and water exchange |
| $^{19}F$ | 1/2 | 94.094 | 100.0% | 0.834 | Sensitive, present in many pharmaceuticals but not in excipients, and large chemical shift range |
| $^{23}Na$ | 3/2 | 26.451 | 100.0% | 0.0927 | Analysis of salts of API acids, also present in excipients |
| $^{27}Al$ | 5/2 | 26.056 | 100.0% | 0.207 | Present in some pharmaceutical excipients and in vaccine adjuvants |
| $^{29}Si$ | 1/2 | 19.867 | 4.67% | 0.000367 | Present in some pharmaceutical excipients |
| $^{31}P$ | 1/2 | 40.480 | 100.0% | 0.0665 | Sensitive, useful for phosphate salts and phosphorus-containing pharmaceuticals, and also present in some excipients |
| $^{77}Se$ | 1/2 | 19.071 | 7.63% | 0.000537 | Useful for characterization of selenium-containing pharmaceuticals |

[a]Values are from Ref. (21).
[b]Relative to $^{1}H$ at 1.0000.

is straightforward. In many cases, the deuterated solvent itself is of interest, if it can be incorporated into drug hydrates and solvates, polymeric excipients, and many other pharmaceutical materials as bound or surface solvent for studies that track moisture or examine its physical state (24–26). Deuterium may also receive increased attention for solid form analysis as deuterated drug molecules advance in clinical development (27).

***2.1.3 Nitrogen-15*** Nitrogen is frequently present in pharmaceutical molecules, in the guise of a wide variety of amino, amido, imino, and heterocyclic functional groups (28), and new applications of nitrogen-containing functional groups in medicinal chemistry are constantly expanding (29). Amines are commonly used to add ionizable groups and affect solubility and membrane permeability, while also allowing the formation of salts (30). The spin 1/2 nucleus $^{15}N$ is commonly studied despite its low natural abundance; extensive tabulations of experimental $^{15}N$ NMR data are available from solution-state NMR studies (31). Typically, $^{15}N$ SSNMR data are externally referenced to either ammonia or nitromethane via solid glycine or ammonium chloride samples (21). Because it has a spin of 1, has a strong quadrupolar broadening, and lacks a central transition, the quadrupolar $^{14}N$ nucleus is not commonly studied by SSNMR; however, new developments in $^{14}N$ SSNMR may ultimately make it accessible for pharmaceutical studies (32). The closely related technique of nuclear quadrupole resonance (NQR) is also emerging as a potential method for analysis of this isotope in pharmaceuticals (33). The effects of the $^{14}N$ isotope are commonly seen in the $^{13}C$ spectra of pharmaceuticals, as are the effects of other quadrupolar nuclei, through residual dipolar coupling effects (34).

***2.1.4 Fluorine-19*** Fluorine is encountered in a growing number of marketed and research pharmaceuticals, particularly because of its ability to improve metabolic stability to common liver enzymes; one analysis from 2002 indicates that 30% of the new chemical entities approved in the United States were fluorinated molecules (35,36). Aryl fluorines and $CF_3$ groups are commonly found in pharmaceuticals. Fluorinated steroid molecules containing aliphatic CF groups are also frequently encountered. With a natural abundance of 100% and a high gyromagnetic ratio, plus high selectivity and freedom from interferences and background (37), $^{19}F$ is an ideal nucleus for high-sensitivity SSNMR analysis of fluorinated API. $^{19}F$ has a wide chemical shift range, covering 1000 ppm, and a relatively high CSA (31,37). Although most pharmaceuticals contain only a few fluorine atoms, there is the potential for strong homonuclear dipolar couplings (37). $^{19}F$ spectra are referenced to liquid $CFCl_3$ via a number of procedures, including ghost referencing, as there is no accepted external solid reference standard (21).

***2.1.5 Other Nuclei of Interest*** $^{31}P$ is another nucleus with a natural abundance of 100% and other generally favorable NMR properties that are useful in pharmaceutical analysis. $^{31}P$ has a chemical shift range covering $\sim$75 ppm for pharmaceutical samples and can have a relatively high CSA. Phosphorus is most

commonly observed in phosphate salts (30) and in some pharmaceutical excipients, although a number of pharmaceutical compounds contain organic phosphorus, including the ACE inhibitor fosinopril (38), fosamprenavir, auranofin, and the osteoporosis medication alendronic acid. Selenium has recently started to appear in drug molecules (39); it has a favorable spin 1/2 nucleus ($^{77}$Se) as shown in Table 1. Colloidal silicon dioxide and other silicate excipients can be probed using $^{29}$Si SSNMR, which has the added benefit of being applicable to studies of stationary phases widely employed in pharmaceutical chromatographic analysis.

Other NMR active nuclei that appear in pharmaceuticals are often quadrupolar isotopes. Sodium is frequently encountered in pharmaceutical materials, both in excipients and in sodium salts of drug molecules, and is amenable to study using $^{23}$Na SSNMR methods (12,40). Boron-containing drugs can benefit from SSNMR studies of the quadrupolar $^{11}$B nucleus, which can readily distinguish trigonal and tetrahedral coordination among other useful parameters (41). Boron-containing drugs have recently been the subject of renewed interest through a growing range of medicinal chemistry approaches, culminating in the recent marketing of bortezomib, an organoboronic acid proteasome inhibitor (42–44). With the advent of higher static magnetic fields, other nuclei commonly found in pharmaceutical salts, such as $^{35}$Cl and $^{79}$Br/$^{81}$Br, have also become accessible (45). Aluminum, accessible via the $^{27}$Al nucleus, also appears in excipients and particularly in the adjuvants used in numerous vaccines (46). Like $^{2}$H, $^{17}$O is a useful probe of water incorporation through solution- or vapor-phase exchange into crystalline and amorphous drugs and excipients and can also be labeled directly into molecules of interest, albeit at a greater expense (24,47,48). Finally, other nuclei of pharmaceutical interest, such as $^{33}$S, may become increasingly accessible as fields continue to trend higher (49).

## 2.2 Experimental NMR Methods

***2.2.1 Instrumentation*** The current design of SSNMR instrumentation closely parallels the technology used in solution-state NMR. As a consequence, most modern SSNMR systems utilize digital filtering and digital signal generation to produce radiofrequency (RF) pulses and detect NMR signals (50–52). Digital receivers have greatly improved spectral baseline while adding dynamic range and sensitivity to modern SSNMR experiments. Direct digital synthesis of RF signals allows very rapid frequency and phase shifts and has made a number of specialized SSNMR experiments of relevance to pharmaceutical analysis far easier to implement, such as fast frequency shifts on the order of $\pm 100$ kHz as used for homonuclear decoupling (see below).

The primary difference between solution-state NMR and SSNMR instrumentation is the probe. Standard MAS probe designs have been available for many years; most are designed to operate in wide-bore (89 mm) NMR magnets. Unlike solution-state NMR probes, SSNMR probes usually employ a single solenoidal inductor for excitation and detection of multiple nuclei (53). The design of the tuning circuit, and in particular its power handling and isolation, is critical to the eventual performance of SSNMR experiments. The engineering of the stator and rotor for

stable, high-speed MAS is also a critical consideration, as is the ability of the probe to change temperatures over a wide range. Sizes of outer diameters of common MAS rotor vary from 7.5 to 2.5 mm and can hold sample masses of 400 to 5 mg depending on the internal volume and the use of restrictor plugs. Static probes are also utilized for specialized applications, including $^{2}$H and $^{17}$O wideline SSNMR (53) and high-pressure and wide-temperature range NMR studies (54). Triple-tuned single-solenoid probes and filters that can simultaneously access $^{1}$H, $^{19}$F, and an X-nucleus with good isolation and excellent power handling, using transmission-line designs, are a recent development of special importance, given in the large number of drug molecules that contain fluorine (55).

A number of innovative rotor and stator designs have been developed recently that have seen immediate applications to pharmaceuticals. MAS stators and rotors that are capable of spinning to speeds between 35 and 70 kHz have been developed for $^{1}$H NMR applications, albeit using very small sample quantities (23,56). Because of the commercial availability of ultrafast MAS probes, $^{1}$H MAS experiments at 70 kHz on pharmaceuticals are now possible. Stator designs that flip up to allow easy sample ingress and egress, for narrow bore (54 mm) NMR magnets, are also commercially available and widely used. Probes containing several spinning modules that can be cycled through the most homogeneous central area of the magnet have also been developed; these can be beneficially applied to samples with long $^{1}$H $T_1$ relaxation times so that sequential experiments can be conducted on the stator at the center point while the others relax, allowing for optimal use of the expensive spectrometer (57).

***2.2.2 Routine Experiments*** The basic experiments used to acquire 1D SSNMR spectra and obtain initial chemical shift information are direct-polarization (DP) and CP experiments (16). In pharmaceutical applications, both are commonly combined with $^{1}$H decoupling and MAS. DP–MAS experiments, also referred to as "single pulse" or "pulse and acquire," are commonly used for high-sensitivity nuclei, including $^{1}$H, $^{19}$F, and $^{31}$P, and have the advantage of being both simple and quantitative (if a sufficient relaxation delay is used); these experiments can also be used to study solution fractions of wet solid samples, as discussed in detail below. However, in general, the relaxation rate and the natural abundance of the $^{13}$C and $^{15}$N nuclei prohibit the routine use of DP–MAS. CP–MAS experiments take advantage of the dipolar coupling of the X-nuclei to abundant spins such as $^{1}$H and enhance the sensitivity and reduce relaxation delay by transferring magnetization from those spins to the less-abundant and sensitive spins, the latter benefit being possible because the relaxation rate is determined by the typically efficient relaxation rate of the $^{1}$H spin bath (16). Magnetization transfer, or contact times, generally range from 1 to 10 ms and can lead to semiquantitative signal intensities (58). CP is also the basis of many 2D NMR correlation experiments.

Because of CSA, and the potential overlap of sidebands with signals of interest at typical field strengths and spinning rates particularly with $^{13}$C SSNMR (such as carbonyl groups with aliphatic groups), sideband suppression methods such as the total sideband suppression (TOSS) method are often applied (59). After the application of CP and TOSS, for example, in $^{13}$C SSNMR, the resulting spectrum contains

signals that can be directly assigned without the potential confusion that occurs with small sidebands. Because the Hartmann–Hahn condition is split into a series of sidebands under the influence of MAS (16), the matching condition can be sensitive to sampling conditions; this effect is ameliorated by the use of ramped-amplitude CP methods (60). Thus, an experiment that is well suited for $^{13}C$ SSNMR in pharmaceutical analysis is the CP–TOSS experiment with a ramped $^{1}H$ or $^{13}C$ contact time pulse.

Decoupling plays a key role in many SSNMR experiments and is particularly relevant to hydrogen-rich pharmaceutical compounds. Currently, the most popular heteronuclear decoupling schemes for pharmaceutical solids (useful for decoupling, for example, $^{1}H$ when observing $^{13}C$) are the two-pulse phase modulation (TPPM) scheme and its derivatives, such as SPINAL-64 (61). In pharmaceutical SSNMR of the $^{13}C$ nucleus, these decoupling schemes perform most efficiently at $^{1}H$ decoupling strengths of $\sim$100 kHz; as a result, smaller diameter MAS probes in the 4–5 mm range are widely used because of their ability to produce RF fields in this range. Homonuclear decoupling schemes that decouple $^{1}H$ nuclei from each other, such as the frequency-switched Lee–Goldburg (FSLG) method, are also in widespread use for observation of $^{1}H$ in both 1D and 2D experiments (62). Windowed sequences are available for direct observation of $^{1}H$ spectra if a full 2D measurement is not desired, particularly using the phase-modulated Lee–Goldburg (PMLG) method (63,64). The performance of homonuclear decoupling schemes at higher MAS spinning rates is becoming more important with the trend toward faster speeds; sequences such as PMLG are known to perform well at speeds approaching 65 kHz (65). Newer $^{1}H$ homonuclear decoupling techniques, such as the DUMBO method, also perform well at high speeds (66).

The forces involved in MAS are known to occasionally interconvert solid forms of certain pharmaceutically related compounds. For example, solvates and hydrates can be interconverted by the centrifugal force or frictional heating of MAS (67,68). The use of cooling in the sample area can help ameliorate these effects, if they occur.

***2.2.3 Spectral Editing and Assignment*** Several spectral editing experiments are available, primarily for identifying $^{13}C$ and $^{15}N$ positions by their number of attached protons. The oldest method for spectral editing in organic solids, and still the most widely used, is the dipolar dephasing experiment (69). This experiment, also known as nonquaternary suppression (NQS), utilizes $^{1}H$–$^{13}C$ dipolar couplings to dephase transverse magnetization during an echo period in the experiment; $^{13}C$ sites with stronger $^{1}H$–$^{13}C$ dipolar couplings dephase more rapidly and are removed from the spectrum. In practice, this experiment eliminates signals from methine and methylene carbons and is useful for isolating quaternary carbon aromatic signals in pharmaceuticals for detailed analysis. An $^{15}N$ version of the NQS experiment is also easily implemented, an example of which is shown in Section 3. A variety of more sophisticated SSNMR spectral editing experiments have been developed over the past 15 years; these are based on polarization inversion (PI) (70) or on multiplicity assignment via *J* couplings (71,72). These experiments allow separation of CH, $CH_2$, and $CH_3$ signals, enabling assignments to be made on

overlapped positions. The primary limitation of these experiments is the need to carefully calibrate the PI period or the need to test a range of *J* delays because of the variable performance of homonuclear decoupling sequences. The main application of these experiments in pharmaceutical SSNMR is to refine $^{13}C$ assignments, particularly in molecules with overlapped aliphatic groups, such as steroids and macrolides, where overlap between CH and $CH_2$ signals is significant.

### 2.2.4 2D SSNMR Experiments for Structural Characterization

Numerous 2D SSNMR experiments are available for the detailed structural characterization of solid materials. A list of the experiments that are both robust enough for routine use and have general relevance to pharmaceutical analysis is given in Table 2. In general, these experiments fall into two primary categories: those that probe the dipolar coupling and those that report on the CST.

Experiments that study the dipolar coupling make use of either the inverse cubic dependence of the direct magnetic dipolar coupling between nuclei or longer range dipolar spin diffusion effects (73). The direct dipolar coupling can be divided into heteronuclear and homonuclear couplings, both of which are applicable to pharmaceutical analysis. Most of these experiments are performed as 2D experiments, which provide a connectivity map between nuclei (74,75). Homonuclear and heteronuclear correlation (HETCOR) experiments can correlate a variety of nuclei, including $^{1}H$, $^{13}C$, and $^{19}F$, in pharmaceutical systems that include polymorphs and cocrystals (76,77). Several examples are given in Table 2. Many dipolar experiments involve the $^{1}H$ nucleus, so that the use of homonuclear dipolar decoupling sequences can be a critical feature of their performance. Spin diffusion effects can also appear during HETCOR experiments and can be useful in detecting molecular association (77), and they can also be suppressed when necessary to focus on direct dipolar transfers (78).

The second subclass of experiment that utilizes dipolar coupling effects, those that rely on spin diffusion (73), is also useful for structural analysis of organic and pharmaceutical molecules (79,80). Long-range distance information can be extracted by modeling spin diffusion rates, such that the proximity of multiple proton positions can be determined from the same experiment. Currently, spin diffusion approaches to crystal structure solution have been confined to molecules that are relatively small in size compared to most pharmaceutical compounds, although they hold promise for larger molecules (81). Because of the challenging nature of the analysis, 2D SSNMR experimental methods used for crystal structure determination are often used in conjunction with computational methods and other experimental approaches (such as XRPD powder solution methods) (76,81,82). The computational methods used for this purpose are discussed in more detail in a later section.

The other major class of experiments involves measurement of the three principal components (PCs) of the CST. The CST provides a measure of the spatial dependence of the chemical shift interaction (83). In powdered samples, as is usually the case for pharmaceutical samples, the three principal components of the CST are accessible; these are designated by $\delta_{11}$, $\delta_{22}$, and $\delta_{33}$. A large number of

**TABLE 2 Summary of 1D, 2D, and Pseudo-2D Experiments Commonly Used in Pharmaceutical SSNMR Analyses**

| Experiment | Short Description | Typical Duration | References |
|---|---|---|---|
| $^{1}$H DQ-BABA | 2D dipolar correlation between hydrogen bonding $^{1}$H and neighboring $^{1}$H nuclei, useful for polymorph interrelationships and cocrystals | 1–2 h | (74,76,77) |
| $^{1}$H spin diffusion with CRAMPS | 2D spin diffusion between $^{1}$H nuclei, with effects ranging up to 30 Å, for structural analysis | 1–2 h | (23,79,80) |
| $^{19}$F (or other X-nucleus) spin diffusion | 2D heteronuclear DARR spin diffusion, for pharmaceutical phase purity assessment | 8–12 h | (146) |
| $^{13}$C-detected $^{1}$H $T_1$ saturation recovery | Determination of the $^{1}$H spin lattice relaxation rates ($T_1$) by indirect detection via the $^{13}$C spectrum, for pharmaceutical phase purity assessment and phase mixing experiments | 12 h | (93) |
| $^{1}$H–$^{13}$C CP-HETCOR | 2D detection of dipolar connectivity between $^{1}$H and $^{13}$C, shows spin diffusion when used with longer ramp-CP mixing (800 μs–2 ms), and useful for polymorph interrelationships and cocrystals | 12 h | (75–77,170) |
| $^{1}$H–$^{13}$C LGCP-HETCOR | Detects dipolar connectivity between $^{1}$H and $^{13}$C, minimizes spin diffusion, and useful for solid form interrelationships and assignments | 12 h | (78) |
| $^{1}$H–$^{19}$F LGCP-HETCOR | Detects dipolar connectivity between $^{1}$H and $^{19}$F for fluorinated pharmaceuticals, minimizes spin diffusion | 1 h | (77,78,155) |
| $^{1}$H –$^{19}$F–$^{13}$C DCP-TOSS | 1D experiment for fluorinated pharmaceuticals, detects dipolar connectivity between $^{13}$C and $^{19}$F. | 8 h | (76,77) |
| $^{13}$C CP-PASS | Chemical shift anisotropy ($^{13}$C) for studies of hydrogen bonding and ionization, and for comparison with calculations | 18–24 h | (59,76,84) |
| $^{13}$C CP-FIREMAT | Chemical shift anisotropy ($^{13}$C) for studies of hydrogen bonding and ionization, and for comparison with calculations | 18–24 h | (77,85) |
| $^{13}$C CP-SUPER | Chemical shift anisotropy ($^{13}$C) for studies of hydrogen bonding and ionization, and for comparison with calculations. | 18–24 h | (86) |

The references given include both the original technical implementations of the pulse sequence and subsequent applications to pharmaceutical or similar organic molecules with spectral interpretation.

experiments have been developed for measurement of the principal components in complex samples, but only a few are suited for pharmaceutical applications. The cross-polarization phase-adjusted spinning sidebands (CP-PASS) method was one of the earlier robust methods to be developed and applied to pharmaceuticals (59,84). CP-PASS has been used for the determination of a pharmaceutical crystal structure from a powdered sample (76). The CP-FIREMAT experiment (85)

also provides a highly accurate method for CST analysis and has been applied to a pharmaceutical cocystal (77). The robust CP-SUPER method has also been demonstrated on organic molecules (86).

Besides these two major classes of structural analysis experiments, other 2D SSNMR experiments are useful for pharmaceutical analysis. In particular, the multiple-quantum MAS (MQMAS) experiment is useful for studies of quadrupolar nuclei with moderate quadrupolar interaction strengths, such as $^{17}O$, $^{23}Na$, and $^{27}Al$ (87,88). The MQMAS experiment produces high-resolution isotropic spectra while also allowing access to quadrupolar parameters and has the added benefit of being easily implemented on most modern SSNMR hardware using fast-spinning probes, including systems optimized for pharmaceutical analysis.

***2.2.5 Dynamics and Relaxation Experiments*** Like solution-state NMR, SSNMR is uniquely capable of the study of motion in pharmaceutical systems. Variable temperature NMR plays a critical role in these experiments, as it readily distinguishes static disorder from apparent disorder actually caused by molecular dynamics. Various NMR relaxation measurements can probe motions of different timescales in pharmaceutical molecules and are useful when dynamic motion in the solid state is of interest (5,16).

Samples with longer $T_1$ times may benefit from the use of paramagnetic relaxation enhancing compounds, such as copper sulfate. However, this generally requires recrystallization of the solid form of interest with the relaxation agent and is thus primarily applicable to readily prepared API forms. The benefits of these approaches are much faster data acquisition; such a benefit has recently been demonstrated for protein samples studied with 2D SSNMR (89).

## 2.3 Data Analysis and Computational Methods

***2.3.1 NMR Data Processing*** SSNMR data processing is similar in many respects to that employed in solution-state NMR, given the requirements of a Fourier transform spectroscopic method. In particular, apodization and linear prediction are both widely used in pharmaceutical SSNMR analyses (90). Linear prediction is extremely useful in 2D SSNMR analyses as it allows enhanced resolution in the $F_1$ dimension, helping to optimize signal-to-noise ratio on longer experiments (90). Similarly, although Hadamard transform-based methods are only in limited use, they allow more efficient 2D data collection in SSNMR (91). More advanced processing methods can be applied when needed to handle data produced by specialized experiments, including those that specifically probe dipolar and quadrupolar interactions (92). For example, experiments that produce exponential decays (such as $^1H$ $T_1$ relaxation measurements) can be analyzed using nonlinear fitting methods or the more sophisticated DECRA method; the latter approach is particularly useful for analysis of pharmaceutical phase mixtures (93).

Lineshape fitting and deconvolution are widely used methods for fitting SSNMR spectra of pharmaceuticals. There are a variety of reasons to fit lineshapes, most notably to extract chemical shift and quadrupolar parameters (quantitative aspects of

lineshape fitting are also of great importance, and they are discussed in Section 2.3.2). The principles of lineshape fitting and general applications to SSNMR have been well documented in the literature (94,95). One of the most common uses of lineshape fitting is to extract CST values from MAS spinning sideband patterns. The major disadvantage of lineshape fitting is that a prior knowledge of the spin system (e.g., the number of nuclei) must be known. Software programs are widely available for this task, including both commercial packages and freely available packages from academic laboratories (96).

***2.3.2 Quantitative Analysis*** Quantitative analysis using SSNMR is readily accomplished but requires special care, as is also the case with XRPD, DSC, and vibrational spectroscopy. SSNMR has an inherent advantage over XRPD, DSC, and vibrational spectroscopy in that the signals observed even in CP experiments are approximately quantitative in nature, and the specificity and resolution is such that the need for multivariate analysis (MVA) is minimized. When quantitative analysis with SSNMR is being performed, relaxation parameters, spectral resolution, and spectral phasing must be considered. Spin lattice relaxation ($T_1$) is one of the most crucial relaxation parameters to consider in a quantitative experiment. A recycle delay of at least five times the longest $T_1$ of all components of a sample will ensure full relaxation, although a delay of three times $T_1$ is sufficient to achieve 95% relaxation. For optimum sensitivity of a particular component, a recycle delay of $1.3 \times T_1$ can be used for a 90° flip angle (13). Quantitative results can still be calculated from the integral of a non-fully relaxed spectrum by considering the Bloch equations of steady-state and equilibrium magnetization (13,97). Quantitative results, without the requirement of a calibration curve, can be obtained from the CP–MAS (or CP–TOSS) spectrum if the $^1$H spin lattice relaxation in the rotating frame ($T_{1\varrho}$) and the CP rate constant ($T_{CH}$) are known (98,99). These parameters can be obtained by fitting the CP intensity at various contact times to a kinetic model, from which an extrapolation to "zero contact time" is obtained (99,100).

A detection limit of about 1% w/w using $^{13}$C CP experiments is achievable in favorable cases. For example, a detection limit of 2–3% w/w was reported for polymorph mixtures of delavirdine mesylate (98), whereas a detection limit of 0.5% w/w was achievable for crystalline forms of neotame (99). The detection limit can be experimentally determined from a sample of known concentration as three times the concentration divided by the signal-to-noise ratio measured on the sample (101). Similarly, the limit of quantitation can be estimated as 10 times the signal-to-noise ratio.

When a sample of interest shows poor spectral resolution, because of a lack of crystallinity or a short transverse relaxation time, deconvolution can be used to retrieve overlapped lineshapes for quantitative purposes. However, excessive line broadening can cause a deconvolution analysis to converge to a false minimum, leading to inaccurate results. In such cases, using the fitted linewidth from another resolved peak in the spectrum and then constraining the linewidth of the unresolved component to the same values may be sufficient to allow recovery of the correct lineshape and improve the accuracy of results. Another difficulty arising with

overlapped peaks is spectral phasing, which is subjective and can affect the quantitative results.

Provided that all influence factors to data quality have been carefully considered, the integral of NMR signal is inherently quantitative and can be used directly for analysis without the requirement of a gravimetric calibration curve. Though linewidths of SSNMR signals are substantially broader than that in solution state, the resolution usually suffices for simple integration methods. In cases where signals of different components are overlapped, for example, in amorphous or disordered materials, deconvolution or other methods may be required to obtain more accurate integrals. An example of theoretical lineshape deconvolution for the quantitative analysis of a mixture of an amorphous and an overlapped crystalline phase is shown in Figure 1. Using this $^{19}$F SSNMR method, it is possible to rapidly quantify levels of amorphous content to approximately 5% w/w using a short experiment time (of typically less than 10 min). This process can also be applied to mixtures of crystalline phases, and additional parameters such as CSA and quadrupolar coupling may also be included in fits as needed.

Finally, two other methods are useful for quantitative analysis. In solution-state NMR, principal component analysis (PCA) (102) and independent component

***FIGURE 1*** *Lorentzian/Gaussian lineshape deconvolution of the* $^{19}$F DP–MAS spectrum of a mixture of 50/50 amorphous and crystalline phases. (a) Experimental spectrum, (b) individual subspectra fitted to the two components, and (c) addition spectrum of the two subspectra. The experimental spectrum was obtained at 8.4 T and 273 K.

analysis (ICA) (103) have been commonly used for quantifying overcrowded spectra of chemical mixtures (104,105) and metabolites (106,107). PCA is a statistical method that analyses a large set of experimental spectra to pull out the PCs, which for SSNMR are generally the pure phase spectra. The magnitude of a PC in an individual experimental spectrum provides a quantitative value for that component. Availability of pure phase reference materials can reduce PCA to ICA, where only a small set of reference spectra are required. The ICA method involves the least-squares regression of a reference spectrum to an experimental data set. PCA has been applied to SSNMR in other areas outside of pharmaceutical analysis (108). An example of the use of ICA for amorphous quantification in a crystalline API is shown in Figure 2. The advantage of ICA is exactly the opposite of theoretical deconvolution; that is, a prior knowledge of the spin system is not required for quantitative analysis, although the

***FIGURE 2*** *Quantification of amorphous content in a crystalline API from a* $^{13}$C CP–TOSS spectrum by least-squares regression of reference spectra (using the ICA method). The top traces show normalized spectra of crystalline (green) and amorphous (blue) reference samples. The bottom trace is an experimental spectrum of a 20% amorphous mixture (black) overlaid with an ICA calculated spectrum (red). Spectra were obtained at 8.4 T and 273 K.

method requires phase-pure reference samples. In addition, caveats for the use of ICA include ensuring that the linewidth and phasing of the references, particularly the crystalline reference, are as similar to the experimental spectrum as possible.

***2.3.3 Prediction of NMR Properties*** Computational methods can reliably reproduce SSNMR parameters from molecular models, such as the chemical shift, the spin–spin coupling, and the electric field gradient (EFG) (109), and greatly facilitate the interpretation of experimental CST and EFG differences between solid phases (110). Computational methods aid in the understanding of molecular conformation, the assessment of hydrogen bonding and π-stacking (76), the assignment of ionization states, the assignment of resonances (111,112), and the elucidation of powder structures (76,113,114), and they can often provide a link between low-temperature crystal structures and room temperature bulk material. Although many studies have focused on the prediction of $^{13}C$ and $^{15}N$ chemical shifts, studies on other nuclei are also useful (109). A brief overview of the computational methods useful for pharmaceutical SSNMR is provided here; more details can be found in recent reviews (109).

Recent improvements in chemical shift prediction in particular have been driven by the availability of computational resources and the further development of theoretical methods. This in turn has enhanced the applicability of these methods to pharmaceutical SSNMR. Although simple Hartree–Fock (HF) calculations are sufficient to reproduce chemical shifts when electron correlation effects are small, such as in the $^{13}C$ shift prediction of aliphatic carbons, post-HF methods are required to accurately predict chemical shifts when correlation effects become significant, as is the case for most molecules of pharmaceutical interest (109). Although expensive perturbation and coupled cluster methods can account for these effects, they are often not applicable to larger molecular structures as encountered in pharmaceutical research and development. As a result, density functional theory (DFT), which also accounts for electron correlation, has been shown to accurately predict chemical shifts and field gradients, especially using hybrid functionals such as B3LYP (109). The computational requirements of DFT methods scale more favorably with the number of electrons ($N^4$), so that computations on typical pharmaceutical molecules are feasible on desktop computers. For Gaussian basis set methods, full double zeta and triple zeta basis sets including polarization and diffuse functions are recommended for reliable results (109).

In addition to improvements in molecular orbital theory, various methods have been developed to include solid-state effects such as steric interactions, long-range electrostatic interactions, collective intermolecular hydrogen bonding, ring current effects, and band structures. These include simple cluster methods (109), as well as methods based on periodic boundary conditions, Ewald summation, Madelung potentials, plane wave basis sets (115), and ONIOM methods with localized basis sets (116). These methods are often needed, since solid-state effects in pharmaceutical compounds can alter the computed wavefunctions and consequently the computed NMR parameters (76,77). The cluster approach includes neighboring molecules in the calculations to describe the intermolecular effects. This approach has been shown to

yield satisfactory $^{13}C$ and $^{15}N$ chemical shifts when only short-range interactions are present, such as steric interactions or intermolecular hydrogen bonding (76,110). Large charge separations within the molecule of interest can result in significant long-range Coulomb interactions. Further improvement over the simple cluster approach may be achieved by including these interactions with the ONIOM method that includes a shell of point charges beyond the molecule of interest. However, the finite size of the point charge array can still lead to significant truncation effects because of the poor convergence of Coulomb lattice sums. The electrostatic interactions in molecular crystals may be included by fitting point charges to reproduce the Madelung potential at an area of interest in which the quantum mechanical calculations are performed, as implemented in the embedded ion method (117). These pure point charge methods are computationally less demanding and can be performed on large unit cells and large molecules with limited computational resources, and they also may be combined with cluster approaches; however, the method again requires a crystal structure and is not commercially available (118).

A full quantum mechanical description of all intermolecular crystal effects can be achieved by periodic boundary conditions and plane wave basis sets (115). Although this approach allows the inclusion of all intermolecular effects that can be modeled by DFT, the method is computationally intensive and requires considerable computational resources, except in cases of small molecules and unit cells. When a crystal structure is available, CST and EFG calculations are possible with these methods, the most notable of which is the gauge-including projector-augmented wave (GIPAW) method, as implemented in the commercially available CASTEP software package (119). The GIPAW method has been applied to pharmaceutical molecules such as flurbiprofen and testosterone to enhance spectral assignments (111,120). As computational resources continue to increase in performance and become more accessible, the application of these methods to pharmaceutical compounds is likely to increase.

## 3 APPLICATIONS

### 3.1 Active Pharmaceutical Ingredient

SSNMR studies of drug substance still represent the predominant use of the technique in the pharmaceutical industry. Although it can be used in the study of chemical structure in the solid state, in cases where a molecule of interest is insoluble or where a particular effect (such as keto-enol tautomerism) must be studied directly in the solid (123), the primary application of SSNMR is in the detailed study of the physical form of molecules for which the chemical structure is already known. SSNMR is thus widely used to support the development of crystallization processes to control the solid form of a drug substance and to understand the solid form itself, including applications to polymorphs, salts, solvates, cocrystals, and amorphous phases. The resolution, specificity, and information content of SSNMR offer many advantages compared to other techniques for API solid-state analysis, including infrared (IR) and Raman spectroscopy, XPRD, thermal methods, and microscopic methods. In this role,

SSNMR is often applied in conjunction with other methods to gain complementary information.

One of the key applications of SSNMR to drug substance is in the determination of phase purity. Polymorphs, salts, solvates, cocrystals, and amorphous forms can all be collectively referred to as phases, where the term phase refers to a single crystalline or noncrystalline entity. A phase impurity is any other physically separated phase that is present besides the desired phase. For example, another undesired polymorph present at the 10% w/w level in a batch of a desired polymorph can be called a phase impurity (particularly if its specific identity as a polymorph is not yet known). In a salt, the presence of a free base form can be called a phase impurity. SSNMR is one of the most straightforward methods for identifying phase impurities when reference standards for the impurities are not available, and it works well in tandem with the other dominant method of assessing phase purity, XRPD indexing (12). The ease of assignment of SSNMR spectra is the reason for this utility. When determining polymorphic purity by SSNMR, the chemical purity of the sample should first be quickly assessed using other analytical techniques such as HPLC or solution-state NMR. Routine $^{13}$C SSNMR spectra can then be obtained, and, if present in the molecule, $^{19}$F and $^{31}$P spectra may also be recorded. A long relaxation delay should be used to ensure that polymorphs of unknown relaxation rates are observed (e.g., 10–20 s). In the resulting spectra, all resonance lines should be assigned to the solid-state structure, bearing in mind that the asymmetric unit may have more than one molecule ($Z' > 1$), that magnetic equivalencies observed in solution-state NMR are generally not observed in the solid state, and that potentially complicated peak splitting may appear for nuclei coupled to quadrupolar nuclei (such as $^{14}$N and $^{35/37}$Cl) (34) and to nondecoupled spin 1/2 nuclei (such as $^{19}$F) (121,122). If all peaks can be assigned, then it is likely that the sample is phase pure. If additional resonances are observed, particularly of low intensity, the resonances need to be assigned to another form or to defects in the crystal lattice. The simplest method to distinguish these two possibilities is to compare SSNMR spectra of multiple batches of API, since the level of a polymorphic impurity is likely to change from batch to batch, whereas the proportion of a lattice defect often remains constant. If several batches are not available, additional SSNMR experiments may be applied to distinguish these situations. A common approach involves measuring $^{1}$H $T_1$ relaxation rates via the $^{13}$C-detected saturation- or inversion-recovery experiment to take advantage of the resolution offered by $^{13}$C SSNMR (93). Since protons in same crystal lattice will have the same relaxation rate, disordered sites can be distinguished from a phase-separated polymorphic impurity. The experiment, however, does not differentiate between two polymorphs with the same relaxation rate. When unassigned resonances are observed in $^{19}$F NMR spectra, either $^{19}$F-detected $^{1}$H $T_1$ relaxation experiments or spin diffusion methods can be exploited. Spin diffusion is not typically applied to $^{13}$C or $^{15}$N due to the low natural abundance of the nuclei, and the resolution in $^{1}$H SSNMR is often not sufficient. When peaks of unknown origin are present in $^{1}$H, $^{19}$F, or $^{31}$P data, a phase impurity can be distinguished from disorder by use of the 2D dipolar-assisted rotational resonance (DARR) experiment (146) or other 2D spin diffusion experiments that utilized RF-driven or proton-driven approaches; if

correlations between the API and a low-intensity resonance of interest are detected, the molecules that cause these shifts exist in the same crystal lattice and structural disorder is the likely cause of the extra signals.

***3.1.1 Polymorphism*** Polymorphism is one of the principal applications of SSNMR in the pharmaceutical industry. Polymorphs are defined as different crystalline structures of the same molecule; they can differ in molecular conformation, packing arrangements, and close contact interactions such as hydrogen bonding. Strictly speaking, polymorphs do not contain any other species, including water, in the crystal structure. In the pharmaceutical industry, knowledge of the polymorphic behavior of a molecule and control of the desired polymorph of an API is needed for regulatory and intellectual property reasons. Therefore, analytical methods that can distinguish and quantify the polymorphic forms are widely used. The chemical shifts and relaxation times measured in SSNMR experiments are sensitive to differences in the local environment of nuclei, and as a result, the SSNMR spectra of polymorphs are usually unique. Numerous reviews of the field of polymorphism in small-molecule pharmaceuticals and the application of SSNMR to its study have appeared, and only a brief summary is given in this chapter to highlight the current trends in the use of SSNMR in polymorphism studies (5,6,124–126). SSNMR has been applied to the analysis of polymorphism in many classes of pharmaceutical compounds, covering virtually every class of compound commonly encountered in modern drug development (5,6,125,126,132,136,137). In all cases, SSNMR has offered high-resolution spectra with analytical specificity similar to that of high-quality XRPD analysis, which is widely recognized as the premier technique in distinguishing polymorphs.

Figure 3 shows a typical example of the $^{13}C$ SSNMR spectra of two polymorphs of a pharmaceutical drug candidate molecule obtained using the CP–TOSS experiment. The spectra highlight the general nature of SSNMR analyses of polymorphs; they are clearly distinguishable from each other and would allow quantification of one form to the other if appropriate criteria are met. Although SSNMR spectra can be used as fingerprints, the chemical shifts are influenced in a known fashion by the solid-state conformation of the molecule and interactions with the neighboring molecules; these effects can be used for more detailed structural examinations, as described later. In principle, any NMR active nucleus in the molecule can be used to distinguish polymorphs, although $^{13}C$ is by far the most widely employed given the organic nature of most pharmaceuticals, and the large number of distinct carbon sites, which enhances specificity (as many sites are available that might show a different chemical shift between polymorphs). Although $^{13}C$ SSNMR has adequate sensitivity for practical data acquisition time (i.e., $<8$ h in most cases), $^{19}F$ SSNMR is considerably more sensitive and can be utilized whenever fluorine is present in the molecule (37,127). Despite this advantage, literature examples showing the use of $^{19}F$ SSNMR in the detection and quantitative analysis of crystalline solids are limited, as probes capable of simultaneously exciting and detecting $^{19}F$, $^{1}H$, and an X-nucleus have only become commercially available in the past 10 years (55). Since the advent

***FIGURE 3*** $^{13}$C CP–TOSS spectra of two polymorphs of an organic molecule illustrating the typical resolution, sensitivity, and information content of the technique in polymorphism studies. Each spectrum required approximately 8 h of acquisition time. Spectra were obtained at 8.4 T and 273 K.

of this hardware, a number of examples illustrating quantitative applications of $^{19}$F SSNMR to polymorphism or discrimination of polymorphs in API have been presented (128,129). An example is shown in Figure 4, where the $^{19}$F SSNMR spectra of four polymorphs of a trifluorinated steroid are depicted. Even though the molecule contains only three chemically distinct fluorine atoms, the polymorphs can be readily distinguished, and the presence of amorphous content is also easily discerned.

Beyond the basic ability to distinguish polymorphs, SSNMR offers a wealth of information about the crystal structure of each form that can be used in the absence of single-crystal X-ray (SCXRD) solutions to study structural relationships between polymorphs. This is particularly useful early in the development before a form has been selected and permits the study of all of the polymorphs including metastable or transient forms that are difficult to crystallize. A simple example demonstrating the sensitivity of SSNMR to crystal structure parameters is shown in Figure 5. The resonances at about 190 ppm are assigned to a single carbonyl carbon in the molecule, yet two NMR chemical shifts are observed in the spectrum of polymorph II (bottom). These resonances arise from structurally unique molecules in the crystal lattice and are referred to as the asymmetric unit ($Z'$) by crystallographers, or the smallest structural unit that, when symmetry is applied, forms the crystal lattice. The two polymorphs shown in Figure 5 have $Z' = 1$ (top) and $Z' = 2$ (bottom). The $Z'$ value is of

***FIGURE 4*** $^{19}$F DP–MAS spectra of four polymorphs and an amorphous form of a trifluorinated steroid. The topmost spectrum shows the spectrum of Form 3 after grinding and contains a large amount of amorphous material. Spectra were obtained at 8.4 T and 273 K.

great utility in indexing an XRPD pattern to obtain crystallographic information (134,135). Typical organic molecules have a $Z'$ of 0.5–4; however, larger values are observed. For instance, the presence of a $Z' = 6$, superlattice was identified by $^{1}$H relaxation measurements, whereas the solution to the X-ray structure was ambiguous (138,139).

The NMR chemical shift is sensitive to small changes in conformation and hydrogen bonding. The latter effect has been particularly well characterized for $^{1}$H, $^{2}$H, $^{13}$C, and $^{15}$N environments and can be interpreted empirically in many cases (140). For example, for carbonyl hydrogen bond acceptors, shorter hydrogen bonds lead to more deshielded $^{13}$C carbonyl resonances (141,142). For the $^{15}$N chemical shift of nitrogen hydrogen bond acceptors, such as pyridine and aliphatic nitrogen groups, shorter hydrogen bonds lead to more shielded resonances (143–145). Conversely, the $^{15}$N chemical shift of nitrogen hydrogen bond donors (e.g., amines and amides) is observed to be more deshielded with shorter hydrogen bonds. These effects have been used in numerous studies to probe hydrogen bonding in pharmaceutical polymorphs, solvates, and hydrates, especially where only limited crystal structure data are available (5,131–133).

The polymorph isolated from a given process may not be the most thermodynamically stable phase, but may be favored kinetically under the conditions of that

***FIGURE 5*** $^{13}$C CP–TOSS spectra of steroid drug before (bottom) and after (top) particle size reduction by micronization (top), illustrating the conversion from a metastable phase to a phase of greater stability. The dotted line highlights a small amount of the residual metastable phase remaining in the final material. Spectra were obtained at 8.4 T and 273 K.

process. Conversion between polymorphs can be induced by application of energy and can be achieved mechanically by particle size reduction or grinding, by heating, or by slurrying. The effect of micronization, a particle size reduction process (130), on a steroid molecule is shown in Figure 5. In this example, the polymorph isolated from the process is metastable, and during the particle size reduction, is almost completely converted to a more stable one.

***3.1.2 Disordered Solid Systems*** The term "disorder" has several meanings in modern pharmaceutical development. One common usage of this term arises from the processing of crystalline pharmaceutical solids, which can frequently lead to crystal defects and amorphous solids (147). Disorder can also be used to refer isolated molecular sites or moieties being in several positions in otherwise well-crystallized lattices. Since SSNMR is highly sensitive to local structural perturbations, it is able to detect all these types of disorder. Disorder in the solid state is of great concern to the pharmaceutical industry because it can lead to chemical stability issues (152,153).

A solid devoid of translational, rotational, or conformational order, and thus has no long-range order, is considered to be an amorphous solid. While some compounds

naturally crystallize in this state, the amorphous state can be induced by poor crystallization conditions or postprocessing of the bulk, such as drying, milling, compression, and micronization. It is common, however, to induce partial conversion, in which regions of purely amorphous and purely crystalline forms coexist in the same batch. In these cases, a convoluted SSNMR spectrum of sharp resonances of the crystalline form and the broad resonances of the amorphous form is observed (5). It should be noted, however, that unlike XRPD where a broad "halo" is observed for the amorphous phase, highly distinct (albeit broadened) resonances are still observed in SSNMR spectra. Further details of SSNMR analyses and the amorphous state in general can be found in numerous studies devoted to the amorphous state (5,148,149) and are also discussed in the context of amorphous dispersions with excipients later.

Disorder can be limited to a functional group such as a phenyl (150) or *tert*-butyl (151) group, or to any included solvate molecules. In these cases, only a few broadened low-intensity resonances of the particular structural moiety are observed in the SSNMR spectra, while the remaining peaks remain sharp. Site disorder can be caused by molecular mobility, and decreasing the analysis temperature can slow down this motion, reducing the broadening of the NMR resonance lines. When the disorder is static and the groups exist in distinct locations, temperature changes will not influence the SSNMR spectrum. In SCXRD, site disorder can be modeled and the atoms are given multiple positions with a corresponding site occupancy factor. However, the nature of the disorder, static or dynamic, cannot be measured directly from diffraction data. In addition, site disorder is not easily discernable by XRPD.

A special example of disorder is a solid solution or a solid whose crystal structure incorporated a structurally similar molecule into the lattice (154). SSNMR is particularly useful in studies of solid solutions, often in a complementary fashion with XRPD and thermal methods (155). Solid solutions involving an API molecule and a structurally related chemical impurity are of interest in pharmaceutical crystallization development, as are disordered crystalline API structures containing inclusions (or occlusions) of solvents or other small molecules; SSNMR analysis can be beneficial in these cases because of its ability to detect disordered regions of an otherwise crystalline material.

***3.1.3 Solvates*** The term solvate is used here to refer to a crystalline solid that has incorporated solvent molecules, including water, into the crystalline lattice. Similar to nonsolvated forms, solvates can be polymorphic (5,6). Solvates and hydrates have been classified in several different ways (156–161); in many cases, it is most useful to consider a continuum of solvation states based on the strength of binding of the solvent to the crystalline lattice. At one extreme, the solvent molecule is strongly hydrogen bound to a defined position in the lattice and typically has a stoichiometric relationship to the parent drug molecule. An illustrative example of the analysis of stoichiometric hydrates using $^{13}C$ and $^{15}N$ SSNMR has been given for three dihydrate polymorphs of olanzapine (162). Channel solvates, in which the solvent is located in channels that run through the lattice, may also have a highly ordered arrangement, but can also be disordered and exhibit variable stoichiometry. The presence of channels provides a mechanism for solvent to be lost and gained

***FIGURE 6*** $^{19}$F DP–MAS spectra of a channel hydrate of a trifluorinated drug with increasing drying time (a–f) and then subsequently exposed to ambient humidity (g–i). The water content for each sample was measured separately and is shown for each point. Spectra were obtained at 8.4 T and 273 K.

according to ambient conditions as the lattice expands and contracts to accommodate more or less solvent. As an example of this type of solvate, Figure 6 shows the $^{19}$F SSNMR spectra of a channel hydrate of a steroid API as a function of its water content. As water is lost and gained through the process of drying and rehydration, the hydrogen bonding in the host lattice changes, as does the lattice spacing, and a continuous change in the appearance of the $^{19}$F resonances is observed. The effect is reversible and as no other resonances appear during the experiment, the lattice is expanding and contracting without collapsing irreversibly to a desolvated phase. A number of SSNMR studies of pharmaceuticals exhibiting nonstoichiometric hydration have been published, illustrating the different approaches to tackling this problem and exemplifying how SSNMR can provide insight into the nature of the solvation processes (24,25,133,163,164). In many cases, SSNMR has the unique ability to directly study the solvent, for example, by observation of $^{1}$H, $^{2}$H, and $^{17}$O nuclei (24,25).

At the other extreme, solvents can be present in larger channels or merely physisorbed to the surface of excipient/drug particles and are very weakly bound. Weak solvates may only exist in the presence of excess solvent (e.g., slurries and wet cakes) and can completely desolvate upon isolation or drying. An example of this is

***FIGURE 7*** $^{13}$C DP–MAS spectrum of a weak methanol solvate (bottom), showing peaks from all methyl groups in the sample. $^{13}$C CP–TOSS spectra of same sample (middle) showing only peaks that are part of the solid lattice-including solvated methanol. $^{13}$C CP–TOSS spectra of this sample dried (top) showing loss of solvated methanol. Spectra were obtained at 9.4 T and 273 K.

shown in Figure 7, where a methanol solvate present in a wet cake sample loses solvent once dried to convert to a desolvated form. $^{13}$C SSNMR can distinguish between solvent bound to the lattice and unbound solvent using DP and CP–MAS experiments. In the DP–MAS spectrum, resonances from all species are observed and the intensity is based on the relaxation rate of the nucleus. Fast relaxing groups such as methyl groups or unbound liquids/solutions with unrestricted mobility are typically observed when using short relaxation delays (30 s or less). Conversely, the signal intensity in a $^{13}$C CP spectrum arises from the transfer of magnetization from $^{1}$H to $^{13}$C, which is disrupted by molecular motion, so that highly mobile solvent resonances are not observed. SSNMR is particularly well suited to studies of weak solvates because it can easily handle wet samples. The detection of weak solvates helps in the interpretation of competitive ripening results often used to establish thermodynamic stability between polymorphs (as the presence of weak solvates can confound the results in multisolvent studies).

***3.1.4 Salts*** It is often desirable to develop a salt of the active molecule either to obtain a crystalline product or to improve the characteristics of the drug such as

solubility or hygroscopicity (30). As such, it is important to establish salt formation or that protonation or deprotonation has occurred. When the salt former contains NMR active nuclei, it can be observed directly by SSNMR, while the occurrence of proton transfer can be established indirectly by the effect protonation or deprotonation has on the NMR chemical shifts of the parent molecule or directly by spectral editing experiments based on attached proton multiplicity. For example, eltrombopag olamine forms a salt with one or two moles of monoethanolamine (MEA), referred to as the mono- and bis-MEA salts, as shown in Figure 8. The compound has two acidic sites, with $pK_a$ values estimated at 4 for the carboxylic acid (C13) and 8.5 for the phenol (C8). The $^{13}C$ CP–TOSS spectra of crystalline MEA salts and free acid are compared in Figure 8. The MEA resonances are observed in the 60–40 ppm range, and the salt formation changes the carboxylic acid chemical shift from 167 to 173 ppm between the free acid and mono-MEA and the phenol (C8) from 142 to 156 ppm upon conversion to the bis-MEA salt.

Since a large number of pharmaceutical compounds contain basic nitrogen functional groups, the formation of an acidic salt can be confirmed by observing the $^{15}N$ chemical shift in the solid state. Unlike other spectroscopic methods, such as vibrational spectroscopy, SSNMR is able to readily locate the site(s) of protonation in a molecule containing various basic groups with suitable $pK_a$ values (165,166). Comparison of the chemical shifts of the nitrogen atoms of free base and putative salt can be informative, but the relative shifts can depend on the chemical environment of the nitrogen. Figure 9a compares the $^{15}N$ CP–MAS NMR spectrum of a free base and a tosylate salt of a drug candidate. In this case, salt formation is suggested by the 16 ppm shift of an amine resonance from −305 to −289 ppm. The minor shifts observed for the other nitrogen sites are related to differences between the crystal structures of the free base and the tosylate; computational methods would be required to resolve this ambiguity. Also, in some instances, it may not be possible to obtain a SSNMR spectrum of the parent molecule for comparison. In those cases, it is possible to establish the protonation state of the nitrogen atom by utilizing the spectral editing pulse sequences described in Section 2, such as dipolar dephasing. For example, the $^{15}N$ dipolar dephasing spectrum in Figure 9b shows a decrease in the intensity of the signal of those nitrogen atoms that are protonated.

When the pharmaceutical salt is a carboxylate, the $^{13}C$ CST can be measured to determine whether protonation has occurred (166–170). Deprontated carboxyl groups will generally yield a $\delta_{11}$ value of less than 250 ppm, while $\delta_{11}$ for protonated groups will generally lie above 250 ppm. These effects must be carefully interpreted, as hydrogen bonding involving the carboxylate group will also influence the CST; theoretical calculations may be necessary to fully resolve carbonyl ionization state questions. In addition to the more typical cases of carboxylic acid and nitrogen base salts, SSNMR is applicable to more complex studies of ionization and salt formation, as shown by its ability to resolve zwitterionic forms of piroxicam even in an amorphous phase (171). Other complex examples of mixed salt and cocrystal phases involving a composite crystal have also been studied (170,172). Recently, SSNMR of the quadrupolar nucleus $^{35}Cl$ (45) has been used to analyze and characterize polymorphs of hydrochloride salts. Although it requires very high magnetic fields,

***FIGURE 8*** *Comparison of the* $^{13}$C CP–TOSS spectra of eltrombopag olamine (bis-monoethanolamine) salt to crystalline forms of the mono-MEA salt and the free acid, showing the chemical shift changed on salt formation. The MEA resonances are observed in the 60–40 ppm range. Spectra were obtained at 9.4 T and 273 K.

the technique is able to identify the number of chlorine sites in the lattice and provides an indication of the hydrogen bonding environment of this nucleus.

***3.1.5 Cocrystals*** Cocrystals represent an alternative to salt formation for the development of APIs and are a key element of the growing field of crystal engineering (173). A generally accepted definition of a pharmaceutical cocrystal

***FIGURE 9*** Demonstration of the analysis of nitrogen ionization states using $^{15}$N SSNMR. (a) $^{15}$N CP–MAS spectra demonstrating typical chemical shift change (red arrow) of a secondary amine ionized by protonation (top) compared to the free base (bottom). (b) $^{15}$N CP–MAS spectrum of a maleate salt (bottom) compared with the dipolar-dephased $^{15}$N CP–MAS spectrum (top) acquired on the same sample. A nitrogen atom is dephased (red arrow) by the strong dipolar interaction with its attached proton, showing the basic site where protonation has occurred. This methodology has the advantage that the information on protonation is available from a single sample, when comparison between a salt and a free base reference sample is not possible. Spectra were obtained at 8.4 T and 273 K.

is a multicomponent crystal made of an API and one or more small organic molecules, such that the components remain in their neutral (non-ionized) forms and interact with each other by hydrogen or other noncovalent interactions; a stricter definition also in use requires the pure components to be solids at room temperature (174). SSNMR is particularly useful for studying the association of the molecules within a cocrystal via many of the approaches already mentioned, particularly through dipolar correlation,

spin diffusion, and hydrogen bonding and ionization effects. Detailed illustrations of the applications of SSNMR methodology to the identification and characterization of pharmaceutical cocrystals have been presented (77,170). Application of $^{13}C$ and $^{15}N$ SSNMR to an unusual case of a nonstoichiometric pharmaceutical L-tartaric acid cocrystal was useful in identifying protonation states and intermolecular interactions (175).

## 3.2 Excipients

A wide variety of excipients are employed as binders, fillers, diluents, disintegrants, lubricants, or preservatives in modern pharmaceutical products, and SSNMR is a useful and popular method for their characterization (176). It is often desirable to closely study the physical and chemical nature of these inactive ingredients in bulk and in formulation. Many small-molecule excipients can exhibit polymorphism and solvation. For example, D-mannitol is often used as a stabilizer for lyophilized pharmaceutical protein-based products. The three known polymorphs of D-mannitol (177) can undergo form conversion depending on the lyophilization conditions (178). The $^{13}C$ CP–TOSS spectra of the polymorphs are shown in Figure 10 and can be used to identify the polymorph present. Excipients can also exist as hydrates; for example, magnesium stearate has four hydration states, a mono-, di-, and trihydrate, and an anhydrous form, although it is typically sold as a mixture of these states. Understanding the phase content of magnesium stearate can be critical in drug development, as studies have shown that the hydration state of magnesium stearate can affect its performance as a lubricant (179). Trehalose is another excipient that is amenable to characterization by $^{13}C$ SSNMR, particularly since it forms a dihydrate and an amorphous form; the latter is not easily detected by diffraction methods. $^{13}C$ SSNMR provides a high-performance method for quantifying amorphous content in trehalose dehydrate (180). A wide variety of semisolids and gels, including lipids, are used as excipients and can display complex polymorphism and mesomorphism (181). For example, $^{13}C$ SSNMR studies of lipids using CP, dipolar dephasing, and $^{13}C\,T_1$ relaxation measurements provided insight into mesomorphism, ordering, and mobility in α- and γ-oleic acid (182). Information of this nature is useful in pharmaceutical development because the complex polymorphism and crystallization behavior of fats and lipids can impact key product performance attributes in drug products, such as softening temperatures in capsules.

Numerous polymeric excipients are used in pharmaceutical products. SSNMR is a widely used technique in polymer science (95), and pharmaceutical polymers can benefit from much of this experience. An example is provided by poly(methyl methacrylate)-based polymers and copolymers, commonly used in tablet film coating preparations, which have been extensively studied by SSNMR methods including relaxation and spin diffusion studies (183–185). Detailed SSNMR studies of a wide range of other polymeric pharmaceutical materials, such as celluloses, amyloses, and cyclodextrins, have also been reported (186–188). In general, SSNMR can provide information on structure, dynamics, miscibility, and phase separation and help relate these to the macroscopic performance of the polymer.

***FIGURE 10*** $^{13}$C CP–TOSS spectra of three polymorphic forms of D-mannitol, illustrating the ability of SSNMR to distinguish the forms of this excipient. Spectra were obtained at 9.4 T and 273 K.

It is well known that many excipients will adsorb water and that the absorbed water dramatically influences the physical properties or stability of excipients or drug products. For example, sodium starch glycolate, a disintegrant, can adsorb ~25% w/w of moisture when exposed to high humidity; this can be directly and selectively monitored by chemical shift changes in the $^{23}$Na SSNMR spectrum (12). SSNMR is relatively unique in its ability to selectively detect the impact of moisture on excipients, whether through its effects on $^{13}$C, $^{15}$N, or other spectra or through direct observation of protic water by $^{1}$H SSNMR or isotopically labeled water by $^{2}$H and $^{17}$O SSNMR (26), and can thus enhance moisture tracking studies involving vibrational and thermal methods.

## 3.3 Drug Product

Analysis of solid drug products can be broken down into three broadly defined categories: determination of the characteristics of the API in formulation, investigations into the performance of the product *in vitro* and *in vivo*, and assessment of physical solid-state stability. The complexity of a modern drug product demands a

multidisciplinary approach, and the versatility of SSNMR makes it a valuable contributor, particularly given the large number of potential transformations that can occur during the formulation process (189).

***3.3.1 Analysis of API Solid Phases in Formulations*** $^{13}$C SSNMR has been used to identify and quantify the API in a variety of drug products (8,191–198), although $^{13}$C SSNMR is intrinsically a low-sensitivity technique; drug loads of less than 5% w/w are difficult to analyze in a reasonable amount of time except in favorable cases. It should be noted, however, that the sensitivity of SSNMR for low-dose formulations has been enhanced using $^{13}$C and $^{15}$N labeling (12,18,198). Figure 11 shows a typical $^{13}$C SSNMR spectrum of a small-molecule API in a tablet dosage form. Drug molecules often contain various aromatic, carboxylic, and heterocyclic functional groups that are absent in excipients, making it straightforward to both assign all the components of an SSNMR spectrum and find regions devoid of excipient resonances. Other solid-state analysis techniques often require detailed analysis or MVA to separate these components; furthermore. Typical XRPD instruments cannot readily detect amorphous phases. There are many areas of drug product analysis where SSNMR has been underutilized, particularly in studies of the role of

***FIGURE 11*** $^{13}$C CP–TOSS spectrum of eltrombopag olamine in an oral tablet dosage form. The excipients and API chemical shifts are identified. The spectrum was obtained at 9.4 T and 273 K.

moisture in API and excipients. The following examples illustrate the potential of SSNMR in these and other drug product applications.

Although $^{13}C$ SSNMR analysis of drug products is routinely used, more sensitive nuclei such as $^{1}H$, $^{19}F$, $^{23}Na$, or $^{31}P$ can be used as alternatives (199) to extend the limit of detection or obtain the necessary specificity. $^{1}H$ SSNMR analysis is not typically utilized in drug product analysis because of dipolar broadening discussed earlier, as well as spectral overlap with excipients. However, Griffin et al. (200) have demonstrated identification of an API in formulation by exploiting the resolution increase offered in certain two-dimensional NMR techniques, specifically $^{1}H$double-quantum (DQ) MAS experiments. The utility of $^{19}F$ SSNMR is particularly relevant to formulations, since excipients do not typically contain fluorine groups; however, there are only limited literature examples of this approach. In one case, $^{19}F$ SSNMR was used to identify and detect amorphous content in 2% w/w tablets of a selective $M_3$ neuronal receptor antagonist (128). In another example, $^{19}F$ SSNMR was used as a limit test in tablets containing 8.3% w/w of API; a limit of 1.5% w/w for undesired forms was achieved from high signal-to-noise spectra (129). Taking advantage of the previously discussed ability of SSNMR to analyze liquid and wet samples, $^{19}F$ CP–MAS was used to investigate the crystalline form of a drug inside a suspension formulation (201).

About 80% of pharmaceuticals are developed as tablets or capsules, but there are many other formulation classes in which SSNMR can be used including ointments, inhaled powders, and solid dispersions. Figure 12 depicts the $^{13}C$ SSNMR spectrum of a 1% retapamulin ointment; the semisolid excipient petrolatum is clearly observed along with the desired polymorph of the API used in this product. In the past few years, numerous improvements in inhaled dry powder formulations have been made. The complexity of the delivery system makes product formulation a crucial attribute and great efforts are made to fully understand the system. Recently, SSNMR was utilized to study the encapsulation of rifampicin with liposomes for an inhalation product. SSNMR provided insight into the order of the lipic acyl chains and location of the rifampicin in the matrix (202).

Formulations that involve solid dispersions of API in a polymer can also benefit from study by SSNMR. SSNMR can help study the degree of mixing of the API and the polymers present (or any other additives, such as surfactants). Because of its ability to detect the association of different molecules over a range of distances via dipolar correlation and spin diffusion methods, SSNMR is particularly useful for understanding the physical state of a solid dispersion, namely, whether it is a solid solution, nanosuspension, or microsuspension (203). Given the amorphous or mixed crystalline–amorphous nature of these materials, SSNMR has an inherent advantage over XRPD analysis. Several examples are available that illustrate the use of different SSNMR approaches in the study of solid dispersions, including 2D CP-HETCOR experiments (Table 2) for studying API molecular conformation in the amorphous dispersion, and static $^{19}F$ studies of mobility (204–207).

In addition to evaluating the final drug product, SSNMR can be used to understand and potentially direct formulation processes in a variety of systems, including controlled release formulations (208). For example, the crystal structure of a

***FIGURE 12*** $^{13}$C CP–TOSS spectrum of a 1% w/w retapamulin petrolatum ointment, illustrating the ability of $^{13}$C SSNMR to detect the polymorph present in a lose-dose topical formulation. The spectrum was obtained at 9.4 T and 273 K.

derivatized pleuromutilin (*trans*-4-aminocyclohexyl (1*S*,2*R*,3*S*,4*S*,6*R*,7*R*,8*R*,14*R*)-4-ethenyl-3-hydroxy-2,4,7,14-tetramethyl -9-oxotricyclo[5.4.3.01,8]tetradec-6-yl imidodicarbonate) possess large-diameter channels that are capable of filling with nonstoichiometric amounts of succinic acid, ranging from 0.5 to 2.0 mol (170). There was concern that the succinic acid could be washed out of the channels during a top spray fluid bed granulation process. In conjunction with XRPD and chromatographic analysis, SSNMR was used to evaluate granules exposed to different in-process moisture levels, drying rates, and final moisture contents. While no changes in the SSNMR were observed with in-process moisture or drying rate, Figure 13 shows the significant change that final moisture content of the granules had on the succinic acid resonances at ~180 ppm. Chromatographic analysis showed that the total succinic acid content was not changed by the granulation process; therefore, the apparent loss of signal intensity in the CP–TOSS spectrum is caused by an interruption of the cross-polarization. Similar behavior was observed in the pure API and is caused by water entering the channels and triggering molecular motion of the cocrystallized succinic acid molecule. On the basis of these data, fluid bed granulation was used for the process, and a specification for the final moisture content was developed.

***FIGURE 13*** *Expanded region of the* $^{13}$C CP–TOSS spectra of derivatized pleuromutilin granules at various levels of final moisture content: (a) 0.79, (b) 1.09, (c) 1.66, (d) 2.24, and (e) 2.69 mol relative to the API. The succinic acid signals appear at approximately 180 ppm. Spectra were obtained at 9.4 T and 273 K.

***3.3.2 Investigation of Drug Product Performance Issues*** Failure of tablets to fully dissolve, or slow dissolution, is a common problem during drug product development, and in some cases, SSNMR can provide insight into the problem. For example, using $^{13}$C SSNMR, a dissolution failure of delavirdine mesylate tablets exposed to high humidity was linked to free base formation (209). The formation of crystalline drug fractions in capsules of SCH 48461, a cholesterol absorption inhibitor being developed as an amorphous form, was linked to a decrease in the dissolution rate (210). Sometimes, the dissolution medium can interact with the tablet, causing apparent dissolution problems. Partially disintegrated tablets can be removed from the dissolution media and evaluated without drying by SSNMR. Figure 14 shows the $^{13}$C SSNMR spectra of a tablet of an API sodium salt pulled from a 0.1 N HCl dissolution medium after 15 min compared to the tablet prior to disintegration. The lactose is dissolved and a resonance at 170 ppm, concordant with the parent molecule, is observed. Since the parent molecule is insoluble, a new dissolution medium was developed for this API. Sometimes, surfactants such as sodium lauryl sulfate (SLS) are added to the dissolution media of poorly water-soluble drugs. Figure 15 shows a partially dissolved API pulled from a dissolution medium containing 50 mM acetate buffer with 0.75% SDS. The resonances at 71 and 32 ppm are related to the SDS; however, two sets of API-like resonances are observed. For example, the peak at 97.9 ppm is consistent with the initial form of the API, but a second peak at 99.1 ppm is also observed. The chemical shifts of these additional peaks were not consistent with the known forms of the API and changes in the chemical shift of peaks assigned to SDS

***FIGURE 14*** $^{13}$C CP–TOSS spectra of (a) a 50 mg tablet pulled from a 0.1 N HCl dissolution media after 15 min and (b) a tablet prior to testing. The arrow shows peaks associated with a phase change of the API (see text). Spectra were obtained at 9.4 T and 273 K.

suggested that a salt or cocrystal may have formed. This was later confirmed by preparation of an authentic SDS salt reference.

Although dissolution failures are not always related to API physical transformations, the ability of SSNMR to analyze complex mixtures (including wet samples) allows it to quickly confirm or deny a potential physical transformation as the cause of a product dissolution failure, representing an important and growing area of use for SSNMR.

***3.3.3 Physical Stability Analysis with SSNMR*** SSNMR analysis of drug products during stability studies can be relevant in several situations. The API may be known to undergo a physical change, and SSNMR may be the best method for observing API in drug product. Even if the API is known to be stable, it may react with excipients in the formulation, or the excipients may induce noninteraction degradation causing stability issues. Although SSNMR does not directly test chemical stability, it can detect many of the reasons behind instability observed during stability testing, particularly if moisture is involved with the underlying process.

Figure 16 shows an example of a desolvation phase transition involving a low-dose API in drug product monitored by $^{19}$F CP–MAS. Two sets of 1 mg tablets were stored

***FIGURE 15*** $^{13}$C CP–TOSS spectra of (a) sodium lauryl sulfate and (b) an API dissolved in a 50 mM acetate buffer with 0.75% SLS for 10 min. In addition to the resonances of the API (starting material), a second set of API-related peaks and SLS resonances are observed in (b); several isolated site resonances are labeled. These extra peaks were later confirmed as the SLS salt of the API. Spectra were obtained at 9.4 T and 273 K.

at 40°C, 75% RH for 6 months with both as-received and dried, low water content excipients. The reduction of the moisture content in the excipients drastically reduced the desolvation of the API. Further efforts to reduce the ingress of moisture into tablets by moisture blocking packaging and desiccation did not prevent the minor desolvation of the API upon stability. Since desolvation was related to the *in situ* release of moisture from the excipients, it became more significant at lower drug loads where the API to excipient ratio is greater. This demonstrates the utility of $^{19}$F SSNMR in the detection of low levels of unwanted forms in low-dose formulations without interference from excipients, and it is an example of excipient moisture uptake causing API physical instability (211).

In addition to stability studies, SSNMR can aid in gaining an understanding of stability phenomena via forced degradation studies and formulation compatibility studies. For example, excipients can engage in ionic interactions with an API. Byrn et al. monitored the acid–base interaction of magnesium oxide with (+) and (±) ibuprofen, showing that the carboxylic acid of (+)-ibuprofen deprotonates to form a magnesium salt at a much faster rate than the racemic mixture (211). A second example involves the use of tartaric acid as an acidifying agent in a formulation for solubility enhancement. During the formulation development, formulations that involved addition of tartaric acid during granulation (intragranular) and postgranulation (extragranular) to a fluorinated free base API were examined. The $^{13}$C CP–TOSS

***FIGURE 16*** $^{19}$F CP–MAS spectra of 1 mg tablets (a) initial and 6 months at 40°C/75% RH stability sample with excipients as received, (b) initial and 6 months at 40°C/75% RH stability sample with low water content excipients. Spinning sidebands are indicated with "ssb." Spectra were obtained at 11.7 T and 273 K.

***FIGURE 17*** $^{13}$C CP–TOSS and $^{19}$F CP–MAS spectra of (a) tablets with 10% w/w intragranular tartaric acid, (b) tablets with 10% w/w extragranular tartaric acid, (c) API free base, and (d) a separately prepared amorphous API tartrate salt. Spectra were obtained at 11.7 T and 273 K.

and $^{19}$F CP–MAS spectra of the resulting tablets with 10% w/w intragranular and extragranular tartaric acid are shown in Figure 17. A significant shift is observed in the methyl signals of the protonated ethylamine group upon salt formation. The observed chemical shift of this methyl group in tablets reveals the formation of an amorphous tartrate salt in the intragranular formulation, whereas tablets with extragranular tartaric acid are still consistent with free base. The $^{19}$F signal provides further evidence for the salt formation through a broad peak for the amorphous tartrate salt. In tablets with intragranular tartaric acid, this broad peak is clearly evident.

## 4 FUTURE DIRECTIONS AND DEVELOPMENTS

The field of pharmaceutical SSNMR continues to advance at a rapid rate. Many of the areas of expected growth have already been demonstrated to some extent, as previously discussed, even if they are not yet fully applied across the industry. However, several new developments in the wider field of SSNMR, not yet applied to pharmaceutical analysis, deserve special mention because of the high likelihood that

they will eventually be utilized to an appreciable extent. These new developments, and several new applications, are described here.

A number of instrumental and technological improvements in the field of NMR continue to offer new possibilities. A general trend toward higher static field strengths offers increasing access to many quadrupolar nuclei of pharmaceutical interest that are currently not in widespread use. Improvements in probe design, such as the high RF fields generated by microcoil designs, can enhance wideline SSNMR of quadrupolar nuclei. Finally, improvements in automation including automatic tuning probes (similar to those available for solution-state NMR) and improved autosampler designs will likely enhance the usage of SSNMR by simply allowing more analyses to be performed for more drug development projects using less instrumentation. Recently, sensitivity enhancements have been obtained by embedding a microcoil inside a specially constructed MAS rotor and spinning the rotor while relying on RF coupling to an outer coil (212). This technique, known as magic-angle coil spinning (MACS), offers sensitivity enhancements for most common experiments. Because of its ease of implementation, it may soon appear as a routine method in many pharmaceutical SSNMR analyses. Cryogenic probe cooling technology, though it is complex, may also ultimately be adapted for routine SSNMR use; experimental designs have already been demonstrated wherein the coil is maintained at 12 K while thermally isolated from the spinning rotor (213). A variety of polarization enhancement techniques are also available, including those that utilize hyperpolarized xenon gas and parahydrogen (214); the main limitation of these techniques is that the enhancement is generally selective, for example, for surfaces, although this can also be considered an advantage for certain applications.

In the realm of applications, several areas warrant mention. SSNMR may be applied to pharmaceutical molecules of ever increasing size and complexity, ranging from large macrolides to oligonucleotides and peptides to proteins and larger molecules. Polymorphism in crystalline proteins has been studied by SSNMR (215); however; the majority of biopharmaceutical products are amorphous in nature. SSNMR has numerous applications and a great potential in studies of amorphous biopharmaceutical products, particularly those manufactured by lyophilization. Gross information about the structure of a large molecule is available from basic $^{13}C$ and $^{15}N$ SSNMR spectra, allowing at least the detection of batch-to-batch variations in tertiary protein structure. SSNMR is sensitive to dynamics through both spectral variation with temperature and various relaxation measurements and thus has potential applications to the study of glass transition temperatures impacting drug product stability (190).

## 5 CONCLUSIONS

Over the past decade, SSNMR has been increasingly utilized for pharmaceutical analysis. It is widely applied in studies of pharmaceutical solids, ranging from detailed structural studies of API forms to analysis of complex drug products and formulations. It is expected that SSNMR will be increasingly applied to studies of

complex drug products as both the sensitivity of the basic experiments and the performance of more advanced experiments continue to increase. The applications of SSNMR in pharmaceuticals closely parallel those in other areas of materials science, and cross-fertilization will likely continue. Applications to more complex APIs, such as peptides, oligonucleotides, and biopharmaceuticals, will also develop in the future as new molecular classes are developed and new formulations and delivery modes are attempted. As drug molecules, formulations, and products evolve, SSNMR techniques will likely evolve with them.

# TARGET SELECTION IN DRUG DISCOVERY

Charles F. Albright
*Bristol-Myers Squibb, Neuroscience Discovery, Research and Development, Wallingford, Connecticut*

## 1 INTRODUCTION

The annual output of the pharmaceutical industry has been relatively constant from 1993 to 2003 with an average of 30 new molecular enties (NME) per year [1, 2]. Only about 10% of these NMEs were directed at novel targets as identified by the Food and Drug Administration (FDA) [1]. This relatively constant output and low innovation has occurred despite a twofold increase in investment by both the National Institutes of Health (NIH) and the pharmaceutical industry [2] as well as dramatic advancements in technology, such as sequencing the human genome, transcriptomics, and expanded small-molecule collections. The combination of the constant output plus increased investment has driven the cost per successful NME from $1.1 billion for the period 1995–2000 to $1.7 billion for the period 2000–2002 [2]. These trends clearly threaten the long-term health of the pharmaceutical industry.

The reasons for attrition of therapeutic compounds have been studied to help understand how to increase the number of NMEs and innovative therapies. Based on an analysis of investigational new drugs (IND) that were abandoned in the period 1981–1992, one study found that compound attrition was due to a lack of efficacy (35%), economics (32%), safety (20%), and other reasons (13%) [3]. In a separate study, data gathered directly from 10 large pharmaceutical companies for the period 1991–2000 showed that attrition was primarily due to lack of efficacy (about 30%) and safety (about 30%) [4]. Taken together, these studies indicate that efficacy, safety, and economics are the major reasons for attrition. Clearly, identifying targets that are well linked to the disease, likely to have an acceptable therapeutic index with respect to mechanism-based toxicity, and appear economically attractive will decrease attrition. This review will focus on these criteria and an additional criterion, chemical tractability, that assesses the likelihood of identifying a compound with the desired pharmacology and pharmacokinetics. While every target in drug discovery brings unexpected challenges, an accurate assessment of targets with respect to these four criteria will help increase the likelihood of developing successful therapeutics. Other reviews with additional perspectives on target selection for drug discovery are available [5–7].

## 2 CRITERION 1: TARGET LINKAGE TO DISEASE

Connecting a target to the disease is the most important criterion for selecting a target for drug discovery. There are several ways to make this connection, including

1. Human clinical results
2. Human genetics
3. Pathway linked to the disease by human clinical results or human genetics
4. Preclinical studies in model systems
5. Target expression perturbion in the disease

In practice, good targets are supported by several of these connections.

### 2.1 Target Linked to Disease by Human Clinical Results

Human clinical results provide the strongest support for a compound and, consequently, its target in a disease. These clinical results can be with an approved compound or a compound that was efficacious but failed in clinical trials for reasons that could be addressed with an improved compound. For instance, a compound that was abandoned due to off-target toxicity or poor pharmaceutical properties may nonetheless strongly link a target to the disease.

Recent results with a calcitonin gene-related peptide (CGRP) antagonist provide an excellent example of target validation with a compound that has pharmaceutical issues. In a clinical study, intravenous administration of BIBN 4096 BS was effective in treating acute migraine attacks [8]. Since intravenous administration is not an ideal delivery method for a migraine therapy, CGRP antagonists that are delivered using a more convenient method, such as oral administration, would be a preferred therapy relative to BIBN 4096 BS.

Positive clinical results with a biological therapy can link a target to a disease that could be targeted with small molecules. For instance, the efficacy of trastuzumab and cetuximab, biologics that bind the ErbB2 and ErbB1 receptor tyrosine kinases, respectively, validated these targets for certain cancers. Based on this validation, small-molecule kinase inhibitors of ErbB1, gefitinib and erlotinib, and ErbB1 plus ErbB2, lapatinib, were developed [9]. In addition, a biologic that prevents the dimerization of ErbB2 with its partners including ErbB1, pertuzumab, has also been developed [9].

When pursuing targets that are linked to the disease by approved therapies, the ability to to differentiate the new therapy from the existing therapies is an important consideration. A lack of differentiation can create economic issues (criterion 4), which will be discussed further in a later section.

### 2.2 Target Linked to Disease by Human Genetics

Familial diseases, where a mutation in a gene causes or significantly contributes to the disease, provide a strong link between the target and the disease. An analysis of the 100 top-selling drugs in 2003 supports this notion [1]. In particular, these 100 drugs were directed toward 43 distinct proteins. Of these 43 targets, 12 targets had mutations in the corresponding gene that caused a monogenic disorder, a disease where a mutation in a single gene was sufficient to cause the disease. Importantly, these therapies are used for patients with sporadic forms of the disease, not just patients with familial forms of the disease. The development of imatinib, an inhibitor of the Abl (V-abl Abelson murine leukemia viral oncogene homolog 1) tyrosine kinase, exemplifies a target where human genetics played a large role in target selection. In particular, 95% of patients with chronic myelogenous leukemia (CML) contain a chromosomal translocation that fuses the breakpoint cluster region (*Bcr*) gene and *Abl* gene, thereby creating a gene that encodes the Bcr-Abl fusion protein [10]. Studies showed that the Bcr-Abl protein functions as a constitutively active tyrosine kinase that increases proliferation and decreases cell death; both effects required the kinase activity of the Bcr-Abl protein. Based on these results, a small-molecule inhibitor of the Bcr-Abl kinase, imatinib, was discovered and developed.

There are over 1800 human monogenic diseases that identify potential targets for therapeutic intervention [11]. While many of these targets are not tractable (criterion 2) or economically viable (criterion 4), attractive targets for monogenic diseases remain. For example, loss-of-function mutations in the gene encoding PCSK9 decrease plasma low-density lipoprotein cholesterol (LDL-C) levels suggesting that PCSK9 inhibitors would be therapeutically beneficial for atherosclerosis [12]. While there are relatively few targets for major unmet medical need that have corresponding monogenic diseases, monogenic diseases will continue to provide an important source of targets for less prevalent indications, such as those eligible for orphan drug status, which will be discussed in criterion 4.

In addition to monogenic diseases, identifying genes that increase disease susceptibility can identify targets. For example, apolipoprotein E (*ApoE*) alleles affect susceptibility to Alzheimer's disease (AD). Of the three common *ApoE* alleles, which include *ApoE2*, *ApoE3*, and *ApoE4*, studies showed that the *ApoE4* gene dosage increased the risk and onset age for AD while *ApoE2* decreased the risk and onset age for AD [13, 14]. Based on these findings, therapeutic strategies aimed at *ApoE4* are being pursued for AD [15]. A large effort to identify new targets at GlaxoSmithKline by gene association studies was recently described [16]. In addition, the HapMap project identified a collection of single nucleotide polymorphisms to detect linkage disequilibrium throughout the genome in multiple populations. The successful completion of this effort [17] should aid the detection of susceptibility loci for all diseases including more complex, polygenic diseases such as schizophrenia. Targets identified due to disease association studies raise issues not encountered with targets identified by monogenic diseases. In particular, association of a target with a disease could indicate that this target only influences the disease in a subset of patients or affects only limited aspects of the disease. Despite these issues, gene association studies offer the potential to greatly expand

the number of high-quality targets for more complex diseases.

### 2.3 Target on Pathway Linked to Disease by Human Clinical Data or Human Genetics

Understanding the pathways affected by targets linked to the disease by human clinical data or human genetics can lead to new targets. The development of HMG-CoA inhibitors, or statins, to reduce cholesterol levels exemplifies this approach. The identification of a mutation in the LDL receptor that greatly increased both plasma LDL-C levels and the risk of myocardial infarction strongly implicated plasma LDL-C levels in atherosclerosis [18]. This finding stimulated the search for methods to decrease plasma LDL levels that subsequently led to statins. In particular, investigators found that the inhibition by compactin of HMG-CoA reductase, the rate-limiting step in cholesterol biosynthesis, increased LDL receptor expression in the liver and thereby decreased plasma LDL-C levels. Positive clinical results with compactin began the development of HMG(3-hydroxy-3-methyl-glutaryl)-CoA reductase inhibitors for humans.

A similar argument is driving much of the current drug discovery effort for AD. In particular, mutations in the genes encoding the amyloid precursor protein, presenilin-1, and presenilin-2 lead to inherited, early-onset forms of AD [19]. An analysis of these mutants has led to the hypothesis that amyloid beta (Aβ42), a peptide formed by the cleavage of the amyloid precursor protein by BACE (beta-site APP cleaving enzyme) and γ-secretase, is essential for the initiation and progression of AD. Presenilin-1, one therapeutic target for reducing Aβ42, forms part of the γ-secretase enzyme that produces Aβ42 and is therefore linked to the disease by a monogenic disease. Other approaches to inhibit Aβ42, including BACE inhibitors, anti-Aβ antibodies, and Aβ42 aggregation inhibitors, are linked to AD due to their role in the Aβ pathway [20].

### 2.4 Target Linked to Disease by Preclinical Studies

Screening for compounds that produce a desired physiologic effect in a disease model was the typical method for drug discovery before the advent of target-based drug discovery [21]. For example, thiazolidinedione derivatives were known to increase insulin sensitivity in rodents [22] for over a decade before it was recognized that they were ligands for peroxisome proliferators-activated receptor γ [23]. The poor success rate of target-based drug discovery and technologic advancements have prompted a resurgence of interest in the discovery of therapeutics and targets using disease models. For purposes of this review, the identification of therapeutics based on their effects in disease models without requiring prior knowledge of the therapeutic target will be termed forward pharmacology. Forward pharmacology can employ both standard cellular assays, such as cytotoxicity or signaling, more complicated cellular assays, such as highly engineered systems [24] or parallel assays for multiple pathways [25], and in vivo disease models. While these forward pharmacology approaches occur without knowing the molecular target, such identification is usually possible using proteomics, genetics, or other methods.

The use of forward pharmacology is advantageous since this approach may identify targets that are either novel or of suspect chemical tractability (criterion 3) based on precedent. The reliance of this method on a disease model is a potential limitation since most human diseases are often poorly modeled. For example, diseases that take decades to develop are typically compressed into months in a rodent. Further, validation of these models is frequently based on known therapies and, therefore, the predictive value of these models for novel targets is unknown. Additionally, assessment of mechanism-based toxicity (criterion 2) requires target identification, which can require a significant effort.

The tractability of genetic studies in model systems, including *Saccharomyces cerevisiae*, *Caenorhabditis elegans, Drosophila melanogaster*, *Danio rerio*, *Mus musculus*, and cultured human cells has stimulated the search for new targets using these systems [26]. These searches can use several methods such as forward genetic screens, forward pharmacology, and RNA interference (RNAi) screens. A retrospective analysis of targets for known drugs using mouse knockouts provides a strong case for the validity of this approach [1]. In particular, the 100 top-selling drugs in 2003 targeted 43 distinct proteins. The mouse gene that corresponded to these human targets was knocked out for 34 of the 43 targets. Encouragingly, the knockout phenotypes for 29 of these 34 genes were judged informative with respect to identifying therapeutic targets. While a similar analysis has not been conducted for other genetic systems, the frequent conservation of protein function in these model systems suggests that results from these systems will usually be applicable to human targets [27].

Genetic approaches to target identification are advantageous since they can rapidly identify novel targets, including an assessment of both efficacy and the potential for mechanism-based toxicity. As for the forward pharmacology approach, the genetic approach depends critically on the assay to identify mutants. An additional problem is that humans may have multiple genes that could perform the function of the gene identified in the model organism. Understanding the role of

these human homologs in the pathogenesis of the human disease can require significant effort.

### 2.5 Target Linked to Disease by Altered Expression in Disease Tissue

The explosion of methods to profile gene and protein expression has stimulated the search for new targets based on expression differences between normal and disease tissue. In particular, transcriptomics, proteomics, and metabonomics have led to a large number of genes, proteins, and metabolites, respectively, that are differentially expressed in disease tissues. While this data can be the basis for further investigation of a target, altered expression by itself only weakly links a target to the disease since it is not possible to determine whether the altered expression is a cause or an effect of the disease.

## 3 CRITERION 2: POTENTIAL THERAPEUTIC INDEX

The potential therapeutic index of a new therapy is the next question that should be addressed once the target is linked to the disease. The therapeutic index is the ratio of the compound concentration/dose needed for efficacy divided by the concentration/dose that causes toxicity. An effective therapeutic requires a therapeutic index significantly greater than unity. While the therapeutic index may be limited by either compound-specific or mechanism-specific toxicity, efforts should be made to understand mechanism-based toxicity at the time of target selection. In parallel, efforts should be undertaken to understand the amount of target perturbation that will be required for a therapeutic effect. A knowledge of likely mechanism-based toxicity can then be used with tool compounds in disease models to estimate the potential therapeutic index.

A phenotypic analysis of mouse knockouts for the target gene is an excellent starting point to determine potential mechanism-based toxicities. Since a retrospective analysis of current therapeutic targets shows that most knockouts provide evidence of the therapeutic effect [1], it follows that most knockouts will also provide evidence of mechanism-based toxicity. The applicability of mouse knockout phenotypes to human therapeutics can, however, be confounded by several factors, including the effect of knockouts on developmental processes, compensation for the knockout phenotype by altered expression of other genes, and differences in gene function between mice and humans. Despite these potential issues, the phenotype of a knockout of the gene encoding the therapeutic target protein should be determined to identify potential mechanism-based toxicities. Tool molecules can also be helpful in identifying mechanism-based toxicities. Multiple tool molecules from divergent chemical series are usually required to differentiate compound-specific and mechanism-specific toxicity.

In most cases, tool molecules are required to determine the amount of target perturbation required for a therapeutic effect. Such tool molecules will usually be available when the target is identified by clinical compounds. For most novel targets, tool compounds of sufficient quality for these studies will be lacking until well into the drug discovery process. In these cases, a genetic analysis may be helpful. For example, heterozygous knockouts can be crossed into disease-relevant models to determine whether a therapeutic effect is observed. A positive result in these studies combined with an understanding of the effect of the heterozygous knockout on activity of the target provides an estimate of the amount of target perturbation required for efficacy. In rare cases, alleles that cause a range of perturbation of target activity may be available for study in either model systems or from human samples.

## 4 CRITERION 3: CHEMICAL TRACTABILITY

The potential to identify an acceptable clinical compound for either small-molecule targets or biologic targets is an important consideration when selecting a new target. The criteria for small-molecule targets and biologic targets differ significantly and will be considered separately.

### 4.1 Small-Molecule Target Tractability

Small-molecule therapeutics must have acceptable potency, selectivity, bioavailability, pharmacokinetics, and pharmaceutical properties. These constraints have limited the number of targets for which successful therapeutics have been developed. The biochemical classes of small-molecule targets have been collated in three recent reviews. In the first review, the targets of all 483 approved therapeutics as of 1996 contained primarily receptors (45%), which were largely G-protein coupled receptors (GPCR), and enzymes (28%) (Table 1) [21, 28]. In a second review, Hopkins and Groom identified 399 targets in the Investigational Drugs Database and Pharmaprojects Database that had compounds with binding affinities below $10\,\mu M$ that complied to Lipinski's rules [29]. Lipinski's rules, which were developed by evaluating successful therapeutics, state that small-molecule therapeutics should contain fewer than 5 hydrogen bond donors, molecular mass less than 500 Da, low lipophilicity ($c \log P < 5$), and less than 10 hydrogen bond acceptors [30]. These 399 targets contained 120 marketed therapeutics that were comprised

**TABLE 1 Small-Molecule Target Classes for Marketed Drugs**

| Target Class | Percentage of Therapeutics in Each Target Class | | |
|---|---|---|---|
| | First Review[a] | Second Review[b] | Third Review[c] |

primarily of receptors (34%) and enzymes (47%) (Table 1). In a third review, authors collated the targets of the 268 successful drugs [31] contained in the Therapeutic Target Database [32] and also found that small-molecule targets were primarily receptors (23%) and enzymes (50%) (Table 1).

While classifying small-molecule targets as receptors and enzymes is helpful, these broad categories mask much of the complexity of small-molecule target classification. To better understand this complexity, Hopkins and Groom [29] took the 399 targets identified above and grouped them into families based on InterPro domains [33]. The InterPro database is an annotated collection of protein domains based on several algorithms for domain identification [33]. These 399 targets represented 130 protein families where nearly half of the targets were represented by 6 families that included GPCRs, serine-threonine and tyrosine kinases, zinc metallopeptidases, serine proteases, nuclear hormone receptors, and phosphodiesterases. A compilation of InterPro domains that are targeted by more than 3 compounds is shown in Table 2. Interestingly, the majority of proteins that contained these 130 InterPro domains did not have small-molecule compounds in the

**TABLE 2 InterPro Domains Targeted by Small-Molecule Therapeutics**

| InterPro Domain Name | Targets per InterPro Domain | Human Proteins with InterPro Domain |
|---|---|---|
| Serine-threonine protein kinase | 22 | 402 |
| Rhodopsin-like GPCR | 92 | 401 |
| Tyrosine protein kinase | 14 | 264 |

*Source*: Based on data from [29].

databases used for this analysis. For instance, only 22 of 402 serine-threonine kinases and 12 of 115 serine proteases contained small-molecule targets. This analysis also revealed a diverse array of targets in relatively small families. For example, HMG-CoA reductase, the target of statin therapeutics, is part of an InterPro family that contains only a single member.

In a separate analysis, Zheng and co-workers identified 268 targets for successful small-molecule therapies and 1267 targets for investigational therapies in the Therapeutic Target Database [31]. Within these targets, they found identifiable drug-binding domains in 190 successful targets and 1035 research targets. These drug-binding domains were then grouped into families using the Pfam database to identify and define protein families [34]. This grouping showed that successful targets contained 88 Pfam domains and research targets contained 357 Pfam domains. About half of the successful and research targets were contained in 11 Pfam families and 24 Pfam families, respectively (Table 3). There was a significant overlap in the Pfam families that were frequently contained in successful and research targets. Not surprisingly, these frequently identified Pfam families, which included GPCRs, protein kinases, and nuclear hormone receptors, were similar to the frequently identified InterPro domains identified by Hopkins and Groom [29] (Table 2).

Taken together, these studies show that about half of small-molecule therapeutics are targeted at relatively large protein families, such as protein kinases and GPCRs, where successful therapeutics were previously identified. Identifying and optimizing leads for these therapeutic classes will frequently be easier since inhibitors of related proteins will often provide useful leads and insight into compound optimization. Challenges within these classes will include identifying selective molecules and ensuring an acceptable intellectual property position. These studies also suggest that about half

of small-molecule therapies will come from protein families that contain relatively few members. Identifying and optimizing leads for these targets is likely to be the largest challenge.

### 4.2 Biologic Target Tractability

Biologic therapeutics can be broadly grouped into three categories: factors, enzymes, and binding proteins. Factors include peptidic hormones, such as insulin, erythropoietin, and growth hormone. Factors are typically agonists, although dominant-negative factors may be possible. Enzymes are used either for enzyme replacement, such as acid β-glucosidase or factor VIIa, or to catalyze the removal of a toxic species formed in a disease state, such as tPA (tissue plasminogen activator) to dissolve a thrombus. Binding proteins include primarily antibodies that neutralize factors, such as anti-TNF (tumor necrosis factor) and anti-VEGF (vascular endothelial growth factor) antibodies, or bind to cell surface proteins, such as anti-ErbB1 and anti-ErbB2 antibodies, to interfere with protein function or recruit antibody effectors. While antibodies represent the bulk of binding proteins, non-antibody-binding proteins have also been developed. A review of the current biological targets that are contained within the DrugBank [35] shows 56 unique targets for biologics that are divided between factors (38%), enzymes (29%), and binding proteins (34%).

The assessment of the chemical tractability of biological targets should include information about target location, required specificity, target amount, and duration of exposure needed. Most biologic targets are extracellular proteins or extracellular regions of plasma membrane-spanning proteins in peripheral tissues since biologics have limited ability to cross membranes. The number of binding sites, required duration of effect, and turnover of the ligand are also important factors. It will be increasingly important to develop models that incorporate these variables to set the design criteria for a biologic [36].

## 5 CRITERION 4: ECONOMIC CONSIDERATIONS

Economic considerations are an important factor in target selection. When selecting a target for drug discovery one must consider whether the resulting compound is likely to generate revenues that will yield an acceptable rate of return on the investment required to discover, develop, and market the therapy. While a detailed financial analysis is neither practical nor needed at the time of target selection, some estimate of the potential revenues and expenses should be incorporated into evaluation of the target. There are scenarios where an acceptable rate of return is not the proper criterion. One such example is the development of therapeutics for developing countries that are funded by nonprofit organizations. In such cases, the magnitude of the unmet medical need and expenses should be considered when evaluating targets.

The expected revenues from a therapeutic agent will be affected by the total market size, market share, price, and exclusivity period. It is usually straightforward to estimate the total market size and exclusivity period for a new chemical entity. Estimating the market share and price are more complicated issues that depend on the magnitude of the unmet medical need that will be addressed by the new therapeutic. In particular, if a new therapeutic addresses a need that is clearly recognized by patients and payors, then a new therapeutic has the potential to capture a significant market share at a premium price even if existing therapies are available. Conversely, if a new therapeutic performs similarly to available generic therapies, then a large market share and premium pricing are unlikely. Recent experience with acetylcholinesterase inhibitors (AChEI) for the treatment of patients with mild and moderate AD illustrates the growing role payors will play in economics. In particular, a meta-analysis of randomized double-blind placebo-controlled clinical trials with AChEIs showed that only 10% of patients responded to these therapies [37]. Based on this analysis, the United Kingdom's National Institute for Health and Clinical Excellence recommended that AChEIs be used only for patients with moderate AD even though they were approved for both mild and moderate AD patients. Clearly, this recommendation may impact the economics of AChEIs since mild AD patients may not use these therapies if they are not reimbursed.

The expected costs for a new therapeutic agent will be affected by development and marketing costs. For each successful therapeutic compound, clinical development is estimated to cost $1.7 billion [2]. Furthermore, only 11% of compounds that enter human clinical studies are successfully registered [4]. Even these typical values vary between indications. For example, oncology drugs have a 5% success rate while cardiovascular drugs have a 20% success rate. In addition to these success rates, development costs will be significantly affected by the clinical stage at which unsuccessful compounds are terminated. Hence, indications where efficacy can be rapidly assessed in the clinic will reduce the cost of attrition due to lack of efficacy. For example, the effect of antiviral therapy on viral load can often be determined after a single administration. In other cases, it may be possible to accelerate registration based on surrogate

endpoints. In particular, drugs may be approved for serious or life-threatening diseases based on surrogate endpoints if the therapy provides significant benefits relative to existing therapy. Several drugs for cancer have received accelerated approval in the past decade based on the endpoints of objective tumor response rates and time to progression, which serve as surrogates for survival [38]. Finally, development costs can be reduced if the therapy targets an orphan indication. While the definition of orphan indication varies between countries, a rare disease in the United States is defined as affecting less than 200,000 individuals [39]. A variety of incentives, potentially including 7 years market exclusivity, tax credits, and accelerated approval, may be available for orphan drugs depending upon the regulatory agency. Interestingly, several widely used drugs, including erythropoietin for anemia and imatinib for CML, were approved as orphan drugs. In the United States, 282 therapies have been approved as orphan drugs in the last 24 years [40].

### 5.1 Selecting Targets for Drug Discovery

In this review, four criteria were proposed to evaluate new targets: linkage to the disease, potential therapeutic index, chemical tractability, and economics. The following questions are proposed as an additional guide to the application of these criteria for new targets:

- How will the new therapy be differentiated from any existing therapies?
- If the target was identified by a monogenic disease, will the new therapy only be applicable for patients with a sporadic form of the disease?
- If the target was identified using genetics in a model organism, how will the corresponding human target(s) be identified?
- How much target perturbation is required for efficacy?
- What are the potential mechanism-based toxicities?
- Would this therapeutic index and the likely mechanism-based toxicities be acceptable for the target indication?
- Is the target part of a protein family for which therapeutics have been previously identified?
- Does the market size justify the development costs?
- At what point in clinical testing will the key clinical issues be addressed?
- Would the therapeutic be eligible for an accelerated approval or orphan indication?

Even the best targets have issues. The ability to identify these issues, develop a plan to address these issues, and apply judgment as to the likely outcome of these issues will have a significant impact on the success of any drug discovery and development effort. Viewed from this perspective, target selection is a process not an event. In particular, as internal and external data become available, targets should be reevaluated with respect to these criteria to determine the appropriateness of continued work.

## ACKNOWLEDGMENTS

# NEW DRUG APPLICATIONS

John S. McInnes
*Center for Medicare, CMS, Baltimore, Maryland**

## 1 INTRODUCTION TO THE U.S. DRUG APPROVAL PROCESS

A new drug must be approved by the U.S. Food and Drug Administration (FDA) prior to marketing in the United States. "New drug" is defined by Federal Food, Drug, and Cosmetic Act (FDCA) § 201(p) as a human drug that is "not generally recognized . . . as safe and effective for use under the conditions prescribed, recommended, or suggested in the labeling" or one that, although recognized as safe and effective, has not been "used to a material extent or for a material time." The Supreme Court has concluded that a drug must have "adequate and well-controlled investigations"† of the drug's effectiveness to not be considered a new drug [1]. Because almost all drugs (unless already FDA approved) do not meet these criteria, they must go through the FDA drug approval process.

There are different approval processes for the different types of products that are regulated by the FDA. This chapter focuses on the application requirements for new human drugs, both through the new drug approval (innovator drugs) and abbreviated new drug approval (generic drugs) routes. The statutory provisions governing these requirements are found in the FDCA. Other drug application processes that will not be discussed include the over-the-counter review process, new animal drug applications, abbreviated new animal drug applications, and biologics license applications. The new drug application (NDA) process begins with evidence development to satisfy the conditions for approval. Clinical studies that are part of that evidence, if performed in the United States (and optionally if performed outside of the United States), require submission of an Investigational New Drug (IND) application.

## 2 INVESTIGATIONAL NEW DRUG APPLICATIONS

Prior to human clinical trials, preclinical investigation of a drug is performed in the laboratory and in animals to determine the drug's potential effects and to determine if the drug is safe for human testing. This testing typically includes both in vitro (in the laboratory outside of the body) and in vivo (in the body of a living organism) studies evaluating a drug's toxicity and pharmacology. FDA notification is not required prior to preclinical testing, but these investigations are subject to FDA regulations known as good laboratory practices. (See 21 CFR Part 58.)*

Commencement of human clinical trials in the United States require the submission of an IND application.

*This chapter was prepared by John McInnes in his personal capacity. The opinions expressed in this chapter are the author's own and do not reflect the view of the Centers for Medicare & Medicaid Services, the Department of Health and Human Services, or the United States government.

†Such investigations are also required for approval of a new drug application [FDCA § 505(d)].

*These regulations apply to the laboratory work and facilities that perform nonclinical studies intended to support a marketing application for FDA-regulated products, including drugs and biologics.

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*

(See 21 CFR Part 312.) The ultimate goal of most human clinical trials is to gather sufficient information about the efficacy and safety of a drug to support an NDA. This is the beginning of the FDA's role in the clinical development of the new drug. The IND provides an exemption from the requirement that a drug be the subject of an approved marketing application prior to shipment of the drug across state lines. Once an IND is submitted, the FDA has 30 days to object to the IND or it automatically becomes effective and clinical trials may begin. (See 21 CFR Part 312.40). However, if the FDA detects a problem with the IND, it may place a clinical hold on the IND, prohibiting the start of the clinical studies until the problem is resolved. Clinical holds are discussed below.

## 2.1 Types of INDs

INDs can be categorized as either *commercial*, meaning that they are filed by companies intent on obtaining marketing approval for a new drug [2] or *noncommercial*, meaning that they are generally for research purposes or to make an unapproved drug available in certain situations and will not support an application for marketing approval. Types of INDs other than the standard commercial IND are described below.

***Research or Investigator INDs*** Research (noncommercial) INDs are submitted by a physician who both initiates and conducts an investigation. The investigator might want either to study an unapproved drug or to study an approved product for a new indication or in a new patient population. The investigator assumes all responsibilities of the sponsor under an investigator IND (21 CFR Part 312.3). In most cases the purpose of a research IND is not to create data to support marketing approval of either a new indication or a new product. Instead, the physician-researcher may want to publish the study or develop data to support use of the drug in a particular protocol.

***Emergency Use INDs*** *Emergency use* INDs are sometimes called either compassionate use or single-patient INDs. These INDs are for emergency use of an unapproved drug when the clinical situation does not allow sufficient time to submit an IND in accordance with 21 CFR §§ 312.23, 312.24. These are most commonly used for life-threatening conditions for which there is no standard treatment. Other situations in which an emergency use IND can be used are for patients who do not meet existing study criteria or when an approved study protocol does not exist.

***Treatment INDs*** *Treatment* INDs make widely available promising drugs for serious or immediately life-threatening conditions during the completion of clinical trials and during FDA review prior to approval. FDA provided examples of "serious" conditions in the IND final rule:

> [The] "serious disease or condition" requirement refers to conditions that have an important effect on functioning (e.g., stroke, schizophrenia, rheumatoid arthritis, osteoarthritis) or on other aspects of quality of life (e.g., chronic depression, seizures). Alzheimer's dementia, Amyotrophic Lateral Sclerosis (ALS), and narcolepsy are specific examples of serious conditions for which FDA has granted expanded access to investigational drugs in the past. [3]

***Screening INDs*** *Screening* INDs allow a sponsor to test several closely related chemical entities in initial clinical trials. FDA defines a screening IND as "[a] single IND submitted for the sole purpose of comparing the properties of closely related active moieties to screen for the preferred compounds or formulations. These compounds or formulations can then become the subject of additional clinical development, each under a separate IND" [4, p. 2]. Section 6030.4 of MaPPs also describes the properties of screening INDs as follows [4, p. 3]:

> Screening INDs are appropriate when single-dose or short-term, repeat-dose clinical trials (3 days of dosing) are proposed using multiple, closely related compounds. The compounds include different salts or esters and active moieties that are slightly different chemically, but appear to be similar in pharmacodynamic properties. The proposed studies could be a single trial with multiple compounds or similar trials involving only one compound (e.g., several PK studies, one for each compound). The number of compounds tested should usually be 5. Normally, the intent of the study is to compare the properties of the closely related active moieties to screen for further development.

## 2.2 IND Application Content

An IND depends upon a successful preclinical development program demonstrating that the drug has pharmacologic activity that justifies further development and is safe enough to commence human clinical trials. The content of the application may be divided into the following categories.*

1. *Preclinical Testing* Animal pharmacology and toxicology studies comprise the essential preclinical data to permit an assessment as to whether the product is reasonably safe for initial testing in

*The content requirements for an IND are discussed at 21 CFR § 312.23.

humans. Also included are any previous experience with the drug in humans (often foreign use).

2. *Manufacturing Information* Manufacturing information pertains to the composition, manufacturer, and stability of, and the controls used for, manufacturing the drug substance and the drug product. This information is assessed to ensure that the company can adequately produce and supply consistent batches of the drug.
3. *Investigator Information* The IND must include information on the qualifications of clinical investigators, that is, the professionals (generally physicians) who oversee the administration of the experimental drug to the study subjects, so that FDA can assess whether the investigators are qualified to fulfill their clinical trial duties.
4. *Clinical Trial Protocols* The clinical trial protocols are the centerpiece of the IND. FDA evaluates the detailed protocols for proposed clinical studies to assess whether the initial-phase trials will expose subjects to unnecessary risks. For later stage studies, FDA also evaluates whether the trials will, if successful, provide evidence for approval of the drug.
5. *Other Commitments* Finally, commitments to obtain informed consent from the research subjects, to obtain review of the study by an institutional review board (IRB), and to adhere to the investigational new drug regulations.

### 2.3 Clinical Trial Phases

During all phases of investigation, both the sponsor and investigators have responsibilities to ensure patient safety and data integrity. Clinical investigations are usually classified as one of four temporal phases. In practice, these phases frequently overlap.

***Phase I Studies*** Phase I studies are designed to evaluate the safety and the side effects of the drug under study and are the initial introduction of an investigational new drug into humans [5]. Phase I studies are usually conducted in healthy volunteers. Their purpose is to determine the metabolic and pharmacologic actions of the drug in humans, the side effects associated with increasing doses, and, sometimes, to gain early evidence on effectiveness. The data obtained in phase I studies about the investigational drug's pharmacokinetics and pharmacodynamics is used in the design of well-controlled, scientifically valid, phase II studies.

Additional questions pursued during phase I studies include drug metabolism, structure–activity relationships, and the mechanism of action of the drug in humans. The total number of subjects included in phase I studies varies with the drug but is generally in the range of 20–80. During phase I studies, Center for Drug Evaluation and Research (CDER) can impose a clinical hold (i.e., prohibit the study from proceeding or stop a trial that has started) for reasons of safety or because of a sponsor's failure to accurately disclose the risk of study to investigators.

***Phase II Studies*** Phase II is the beginning of evaluations of therapeutic efficacy [21 CFR § 312.21(b)]. Phase II studies are designed to evaluate efficacy and the dose range for the drug, including early controlled clinical studies conducted to obtain some preliminary data on the effectiveness of the drug for a particular indication or indications in patients with the disease or condition. In addition, more information is obtained on short-term side effects and risks associated with the drug. Phase II studies are typically controlled, closely monitored, and conducted in a relatively small number of patients, usually involving several hundred people. An important purpose of phase II trials is to determine the regimen and drug dose or doses for phase III trials.

***Phase III Studies*** Phase III studies are expanded controlled and uncontrolled trials relative to phase II. These trials build upon initial evidence of effectiveness of the drug obtained in phase II and are intended to gather the additional information about effectiveness and safety that is needed to evaluate the overall risk–benefit relationship of the drug. Phase III studies also provide an adequate basis for extrapolating the results to the general population and including that information in the physician labeling. Phase III studies commonly include several hundred to several thousand people.

In both phases II and III, CDER can impose a clinical hold if a study is unsafe (as in phase I) or if the protocol is clearly deficient in design in meeting its stated objectives. Great care is taken to ensure that this determination is not made in isolation but reflects current scientific knowledge, agency experience with the design of clinical trials, and experience with the class of drugs under investigation.

***Phase IV Studies*** Phase IV studies are done postapproval. Although FDA can seek phase IV commitments from a sponsor prior to or after approval, it has until recently been able to require postapproval studies only for drugs approved under the accelerated approval program, which is referred to as the Subpart H Program because the governing regulations are located at 21 CFR Part 314 subpart H.

More recently, the FDA Amendment Acts of 2007 [6] provide the FDA with new authority to require

postapproval studies or clinical trials, as well to require labeling changes for approved drug products. The FDA will now have the authority to require a postapproval study or clinical trial of a drug to assess a known serious risk, or signals of a serious risk, and to identify an unexpected serious risk. Studies or trials are only to be required if the Secretary of Health and Human Services (HHS) determines that current reporting and the postmarket risk identification analysis system are not sufficient to address the concern. For each required study or trial, the Secretary will require a timetable for its completion and periodic reports on status. A responsible person may appeal a requirement under FDA's normal dispute resolution procedures.

### 2.4 Institutional Review Boards

One of the most significant clinical trial subject protections is the Institutional Review Board (IRB), which is required for every clinical trial to ensure the rights and welfare of the trial subjects both before and during their trial participation. IRBs at hospitals and research institutions throughout the United States make sure that participants are fully informed of the risks associated with the experimental treatment and have given their written informed consent prior to commencement of the study.

An IRB must be composed of no less than five experts and laypeople with varying backgrounds to ensure a complete and adequate review of activities commonly conducted by research institutions. In addition to possessing the professional competence needed to review specific activities, an IRB must be able to ascertain the acceptability of applications and proposals in terms of institutional commitments and regulations, applicable law, standards of professional conduct and practice, and community attitudes. Therefore, IRBs must be composed of people whose concerns are in relevant areas. IRBs are monitored by the FDA, and the regulations governing IRBs are at 21 CFR Part 56.

### 2.5 Clinical Holds

FDA may halt or forestall a clinical investigation through a "clinical hold," which FDA uses when it does not believe, or cannot confirm, that the study can be conducted without unreasonable risk to the subjects [7]. If such a determination is made, FDA will contact the sponsor to order it not to start, or to stop, the clinical trial. Clinical holds may either delay the start of an early-phase trial on the basis of information submitted in the IND or stop an ongoing study based on a review of newly submitted clinical protocols, safety reports, protocol amendments, or other information. When a clinical hold is issued, a sponsor must address the issue that is the basis of the hold before the order is removed.

## 3 FULL NEW DRUG APPLICATIONS

Section 505 of the FDCA describes three types of new drug applications: (1) an application that contains full reports of investigations of safety and effectiveness under § 505(b)(1), (2) an application that contains full reports on safety and effectiveness but where at least some of the information required for approval comes from studies not conducted by or for the applicant and for which the applicant has not obtained a right of reference under § 505(b)(2), and (3) an application that contains information to show that the proposed product is identical in active ingredient, dosage form, strength, route of administration, labeling, quality, performance characteristics, and intended use, among other requirements, to a previously approved product under § 505(j).

Right of reference or use [the absence of which may make an NDA a 505(b)(2) application] is defined as "the authority to rely upon, and otherwise use, an investigation for the purpose of obtaining approval of an application, including the ability to make available the underlying raw data from the investigation for FDA audit, if necessary" [21 CFR 314.3(b)]. Sponsors have the right of reference to any studies: (1) they conduct, (2) that are conducted for them, or (3) for which they formally obtain a documented right of reference. An applicant is not considered to have a right of reference to published studies because the applicant does not have access to the raw data. However, if the raw data are in the public domain, a right of reference is unnecessary [8].

The subject of this section is the first type of application that contains full reports of investigations of safety and effectiveness, which are known as full NDAs. The two other types of applications, 505(b)(2) applications and 505(j) applications, also known as abbreviated new drug applications (ANDAs), are discussed in subsequent sections of this chapter.

### 3.1 Process for Full NDAs

***Background—Application User Fees*** In 1992, Congress enacted the Prescription Drug User Fee Act of 1992 (PDUFA). One significant purpose of PDUFA was to decrease review times for new drugs through new FDA staffing and other infrastructure funded by industry-paid user fees. This legislation was reauthorized in 1997 (PDUFA II) as a part of the Food and Drug Administration Modernization Act (FDAMA) and again in 2002 (PDUFA III).

PDUFA was most recently reauthorized in 2007 as title I of the Food and Drug Administration Amendments Act of 2007 (FDAAA). User fees collected under PDUFA IV are to be dedicated to expediting drug development and human drug application review, including postmarket drug safety activities.

PDUFA IV's scope is greater than the original PDUFA mandate of providing the FDA with additional resources for the review of new drug applications. PDUFA IV expands the FDA's use of user fee funding to include collecting, developing, and reviewing safety information (including adverse-event reports), developing and using adverse-event data collection systems, developing and using improved analytical tools to assess potential safety problems, and complying with other requirements related to postapproval studies, clinical trials, and labeling changes. PDUFA IV raises fee revenue amounts to $392.8 million for fiscal year 2008 and includes adjustment methods for fiscal years 2009–2012. It also provides for an additional $225 million in fees for fiscal years 2008–2012 for postmarket drug safety activities.

***Time Constraints on FDA Review*** The FDCA states that FDA must either approve an NDA or issue a notice opportunity for hearing on a proposed denial of approval within 180 days after the "filing" of the application [FDCA § 505(e)]. However, this 180-day limit does not mean that final approval is granted by the FDA within 180 days of submission of the NDA. Although the PDUFA legislation, discussed above, has generally decreased review times for new drugs, the process from start to completion generally takes longer.

There are two overlapping 180-day time periods that govern the NDA review process. The first of these time periods, sometimes referred to as the "review clock," begins at the date of submission of the application and ends 180 days later (assuming that the application is not determined to be ineligible for filing within the first 60 days after submission) [21 CFR § 314.100(a)]. At the end of the 180 days FDA must send the applicant an "action letter." The types of action letters are described in the next section.

The other 180-day time period is sometimes referred to as the "filing clock" [21 CFR § 314.101(a)(2)]. This time period begins 60 days after FDA's receipt of the application unless the agency determines that the application is facially deficient and should not be filed. Such a determination is called a refuse-to-file (RTF) action. The agency must either approve the application or issue a notice of an opportunity for hearing by the expiration of the 180-day filing clock. The 60 days for the filing decision plus the 180 days gives FDA a total of 240 days to process an NDA. This time limit is frequently extended by the applicant filing supplements to the NDA, but even properly extended filing clock time limits can be challenging for FDA to meet.

***FDA Decisions on the Application*** The FDA's official decision on an NDA is termed an "action letter." There are three types of action letters: (1) an approval letter, (2) an approvable letter, or (3) a not approvable letter.* An approval letter indicates final positive action on the NDA, although it may be issued on the basis of draft labeling (21 CFR § 314.105).

An approvable letter is provided for an application that substantially meets the requirements for approval but has relatively minor deficiencies (23 CFR § 314.110). Such minor deficiencies typically relate to the final labeling. An applicant must respond to the approvable letter within 10 days, otherwise the application will be considered withdrawn. The applicant's response can take one of several forms [21 CFR § 314.110(a)]:

- File a resubmission (or amendment) or a notice of intent to file a resubmission to satisfy the remaining requirements for approval (the FDA has 45 days to review an amendment) [21 CFR § 314.110(a)(1)].
- Withdraw the application.
- Request a hearing on whether grounds exist for denying approval when conditions for marketing in the approvable letter are unacceptable.
- Agree to a review period extension to provide more time for the applicant to decide which of the above options to pursue.

An applicant also has 10 days to inform FDA of its intentions when it receives a not approvable letter. Options for the applicant [21 CFR § 314.120(a)(1)–(3)] include:

- Amend the NDA.
- Withdraw the application without prejudice to later refilling.
- Request an opportunity for a hearing on the basis of the agency's failure to approve the application (the agency must issue a notice of an opportunity for a hearing within 60 days of the date of the not approvable letter) [21 CFR § 314.120(a)(3)].

*FDA issued a proposed rule that would amend the regulations on marketing approval of new drugs to discontinue the use of approvable and not approvable letters when taking action on a marketing application and instead use "complete response" letters (69 *Fed Reg* 43357, July 20, 2004). The agency has yet to issue the final rule.

- Agree to a review period extension to provide more time for the applicant to decide which of the above options to pursue.

### 3.2 Application Content

The contents of an NDA are both detailed and extensive, with application lengths running into the tens of thousands of pages. A full NDA contains the following information.

***Safety and Effectiveness Data*** Safety and effectiveness data are the heart of the NDA. Safety data required for the submission includes the following:

1. Pharmacologic properties relating to potential adverse reactions [21 CFR § 314.50(d)(2)(i)]
2. Animal toxicology studies [21 CFR § 314.50(d)(2)(ii)]
3. Studies related to a drug's particular mode of action or conditions of use [21 CFR § 314.50(d)(2)(ii)]
4. Reproduction and teratology studies [21 CFR § 314.50(d)(2)(iii)]
5. Studies on drug absorption, distribution, metabolism, and excretion in animals [21 CFR § 314.50(d)(2)(iv)]
6. Human safety data, including:
   a. Pharmacokinetic and bioavailability data [21 CFR § 314.50(d)(3)]
   b. Clinical pharmacology data [21 CFR § 314.50(d)(5)(i)]
   c. Other safety information such as adverse reactions and drug–drug interactions [21 CFR § 314.50(d)(5)(vi)(a)]

As mentioned earlier in this chapter, the effectiveness data required for approval must be obtained from "adequate and well-controlled . . . clinical investigations" [FDCA § 505(d)]. In the past, FDA interpreted the plural "studies" to mean that two studies were required for approval, but current law permits one study when FDA considers one study to be sufficient. The characteristics of an adequate and well-controlled study are set out in an FDA regulation (21 CFR § 314.126). Well controlled refers to the comparison group relative to the group taking the experimental drug. The control group can either take a placebo (sugar pill) or another drug that is an established treatment for the underlying disease (active control). In other circumstances, dose comparisons, no treatment controls, or, rarely, historical controls may be accepted. The protocol, statistical analysis plan, and an analysis of the data must be submitted with the NDA [21 CFR § 314.50(d)(5)(ii)]. Any additional information and data relevant to safety or effectiveness, including data from uncontrolled studies, must also be submitted as part of a complete NDA.

***Patent Information*** All NDAs are required to include patent information (number and expiration date) for every patent that claims either the drug covered by the NDA or a method using that drug—that could form the basis of an infringement claim if a generic copy of the drug were marketed [FDCA § 505(b)(1)]. Patents for methods of manufacturing the drug are, however, not to be submitted [21 CFR § 314.53(b)]. Other types of patents that should not be submitted in an NDA include: (1) drug packaging patents, unless part of the "finished dosage form" approved in the NDA [9]; (2) patents on metabolites of the drug; (3) patents on intermediates; and (4) method of use patents for methods not approved in the NDA [21 CFR § 314.53(b)(1)].

Patents covering use, the drug product, formulation, and composition must claim the specific drug described in the NDA [21 CFR § 314.53(b)(1)]. However, patent holders can list patents for alternative polymorphs* [10] provided that they certify that the following information exists for the polymorph at the time of submission of the patent information [21 CFR § 314.53(b)(2)(v)].†

- A full description of the polymorphic form
- The executed batch record of the polymorphic form and documentation that the batch was manufactured under cGMP (current good manufacturing practices) requirements
- Demonstration of bioequivalence between the polymorph and the form of the drug product described in the NDA
- A list of all components used in making the polymorph and other manufacturing information
- Comparative in vitro dissolution testing on 12 units each of the batch of drug containing the polymorph and the form of the drug covered by the NDA

The decision as to whether to perform this testing for a polymorph depends upon the perceived advantages of listing the patent for the polymorph (in addition to all of the other patents listed).

*Polymorphs are different physical forms of a pharmaceutical solid. Polymorphic forms usually refer to crystalline and amorphous forms as well as solvate and hydrate forms.

†These data must exist in the patent holders file but need not be submitted to FDA.

### *Risk Evaluation and Mitigation Strategies*

*New REMS Requirements under FDAAA* Section 901 of FDAAA provides a statutory framework for integrating risk evaluation and mitigation strategies (REMS) into NDA reviews and postmarket pharmacovigilance (FDCA § 505-1). These provisions are an evolution from PDUFA III, which provided funding for development of FDA risk management guidance documents and review of voluntary risk minimization plans. Many of the risk minimization tools described in FDAAA are already in use in existing drug approvals [i.e., under Subpart H/Risk Minimization Action Plans (RiskMAPs)].

Unlike earlier versions of the legislation, the final FDAAA provisions do not impose a REMS on *all* drugs and biologics prior to approval. Under the new law, the secretary (in consultation with the office responsible for reviewing the drug and the office responsible for the drug's postapproval safety) may determine that an REMS is necessary to ensure that the benefits of the drug outweigh its risks [FDCA § 505-1(a)(1)]. (In making decisions relating to REMS, the FDA decision makers must be at a level at or above that of an official authorized to approve the NDA.) [FDCA § 505-1(a)(2)(B)(4)]. FDA may also require an REMS for new drug and biologic license applications, drugs and biologics that have already been approved, and for supplemental applications seeking approval of a new indication [FDCA § 505-1(a)(2)(A)]. The holder of a covered application has 120 days to submit its proposed REMS from the time it is notified by FDA that an REMS is required [FDCA § 505-1(a)(2)(B)].

An REMS must include a timetable for the submissions of assessments of the REMS (assessments after 18 months, 3 years, and 7 years, although FDA may eliminate assessments after the 3-year period if the serious risks of the drug are being adequately managed) [FDCA § 505-1(d)]. Additional REMS elements may also be required by FDA: (1) a medication guide and/or patient package insert for distribution to patients [FDCA § 505-1(e)(2)] and (2) a communication plan to health care providers (e.g., sending letters, disseminating information to health care providers directly or through professional organizations) [FDCA § 505-1(e)(3)]. FDA may also require "such elements as are necessary" to assure a drug's safe use if, because of its "inherent toxicity or potential harmfulness," it is associated with a serious adverse drug experience and could be approved only if (or withdrawn unless) the elements are made part of the REMS [FDCA § 505-1(f)(1)].

Furthermore, these REMS elements must [FDCA § 505-1(f)(2)]:

- Be commensurate with the drug's risk.
- Be publicly posted, with an explanation by FDA, within 30 days of the date they are imposed.
- Conform with elements of other drugs with similar serious risks.
- Be designed to be consistent with established systems for distributing and dispensing drugs.

The REMS elements are not to be unduly burdensome on patient access, especially with respect to patients with serious or life-threatening diseases or conditions, or patients who have difficulty accessing health care. The elements must also include one or more goals to mitigate a specific risk listed in the drug's labeling and may require that [FDCA § 505-1(f)(3)]:

- Prescribers have certain training or certification.
- Settings that dispense the drug be certified.
- The drug be dispensed only to patients in certain settings (e.g., hospitals).
- The drug be dispensed with documentation of safe-use conditions (e.g., laboratory tests).
- The patient be subject to monitoring.
- Each patient using the drug be enrolled in a registry.

The elements may also include a system in which the applicant would be required to take reasonable steps to monitor, evaluate, and improve implementation of required elements by providers and other parties in the health care system responsible for implementing the elements [FDCA § 505-1(f)(4)]. FDAAA provides a waiver of these requirements for a qualified countermeasure in the case of a public health emergency [FDCA § 505-1(f)(7)]. Under the new law, the Drug Safety and Risk Management Advisory Committee will seek input from patients and providers about the elements, as well as evaluate the elements of at least one drug, to ensure access and minimize the burdens [FDCA § 505-1(f)(5)]. The committee will also use the input and evaluations to issue guidance and modify elements [FDCA § 505-1(f)(5)(B)].

*FDA Action on REMS* The FDA, after consultation with the office responsible for reviewing the drug and the office responsible for postapproval safety of the drug, must promptly review all proposed REMS and each assessment of an approved REMS [FDCA § 505-1(h)]. No later than 60 days from the submission of the REMS (or 30 days if FDA determines there may be cause for withdrawal of the drug), FDA must initiate

discussions with the responsible person [FDCA § 505-1(h)(2)]. FDA will either describe any required REMS as part of the action letter on the application or issue an order within 90 days of beginning discussions. Any action letter or order will be made publicly available [FDCA § 505-1(h)(3)].

When a concern about a serious risk of a drug may be related to that drug's pharmacological class, FDA may defer assessments of the approved REMS until having convened one or more public meetings to consider responses to the class-based concern [FDCA § 505-1(h)(7)]. FDA must provide notice of the deferral to the holder within 5 days, publish notice in the *Federal Register*, and publish notice of any public meetings [FDCA § 505-1(h)(7)(B)(ii), (iii)]. The meetings may include discussion with the responsible person, meetings of advisory committees, or workshops of scientific experts and other stakeholders [FDCA § 505-1(h)(7)(C)]. After considering the discussions in the meetings, FDA may announce a planned regulatory action in the *Federal Register*, seek public comment, and then issue an order [FDCA § 505-1(h)(7)(D)].

*Dispute Resolution for REMS* FDAAA also sets up REMS dispute resolution procedures [FDCA § 505-1(h)(4), (5)]. If the REMS was submitted at initial approval and there is a dispute about it, then major dispute resolution procedures previously established under PDUFA and FDA guidance would apply. For all other disputed REMS, the responsible person may request that the Drug Safety Oversight Board (DSOB) review the dispute [FDCA § 505-1(h)(5)(B), § 505-1(j)]. The DSOB is composed of federal employees who are scientists and health care practitioners and appointed by the Secretary and will meet at least once each month. Although a determination by FDA that an REMS is required is not subject to review, the particular elements of an REMS may still be reviewed. Under this procedure, FDA must publish notice that a dispute is to be reviewed by the DSOB. Entering into dispute resolution does not preclude further discussions or the use of FDA's administrative appeals, although the responsible person must either withdraw the request for review or terminate the use of administrative appeals. Both parties make a written or oral presentation to the DSOB. The meeting is to be recorded and then made public within 90 days. The DSOB may add members with relevant experience from FDA or other public health agencies for a meeting. No more than 5 days after the meeting, the DSOB will provide a written recommendation to FDA on how to resolve the dispute. The recommendation must also be made public. FDA must issue an action letter or order that resolves the dispute before the action deadline for the action letter on the application or 7 days after receiving the DSOB recommendation.

A drug will be considered misbranded if the responsible person does not comply with an REMS requirement [FDCA § 502(y), (z)]. The law establishes civil monetary penalties of $250,000 per violation, not to exceed $1 million [FDCA § 801(b)(4)]. If a violation continues after FDA provides written notice to the responsible person, a civil monetary penalty of $250,000 for the first 30-day period may be imposed, doubling for each subsequent 30-day period, not to exceed $1 million in a 30-day period and $10 million for all violations adjudicated in a single proceeding. FDAAA requires that the FDA Commissioner report to Congress on how best to communicate to the public the risks and benefits of new drugs. The Commissioner may consider the possibility of using a symbol indicating that the drug was recently approved in the labeling and in any direct-to-consumer (DTC) advertisements.

***Pediatric Assessments*** FDAAA reauthorized the Pediatric Research Equity Act (PREA), so it now will expire in 2012. Under the PREA, an NDA or supplement must be accompanied by a pediatric assessment [FDCA § 505B(2)]. If the assessment indicates that the treatment for the disease has a similar course in all adult and pediatric populations, FDA may conclude that data supporting pediatric effectiveness can be extrapolated from adequate and well-controlled studies in adults or from one pediatric age group to another.

In addition to a reauthorization of the existing requirements, FDAAA significantly expands the PREA's procedures for deferring pediatric assessments. In order for an applicant to obtain a deferral, the applicant must submit a timeline for completion of pediatric studies. Following a deferral, the applicant will each year provide FDA with information detailing the progress made in conducting the studies, and if no progress has been made, evidence and documentation will be provided that such studies will be conducted with due diligence at the earliest possible time. The information will be available to the public through FDA's website. FDA retains the power to grant a full or partial waiver from the PREA assessment for good cause.

The FDAAA also formalizes dispute resolution procedures followed when FDA requests a labeling change to incorporate pediatric information [FDCA § 505B(g)(1)]. If the sponsor disputes the proposed change and the FDA Commissioner and sponsor are unable to reach an agreement on the appropriate changes to the labeling for the drug, then not later than 180 days after the date of the submission, the Commissioner will request that the sponsor make any labeling change that the Commissioner determines to be appropriate. If

the sponsor does not agree within 30 days to make the requested change, the Commissioner will refer the matter to the Pediatric Advisory Committee. Within 90 days of receiving the referral, the Pediatric Advisory Committee will review the pediatric study reports and make a recommendation to the Commissioner. Within 30 days of receiving the Pediatric Advisory Committee's report, the Commissioner will make a renewed request for a labeling change. If the sponsor does not agree to make a labeling change, the commissioner may deem the drug to be misbranded.

Not later than 210 days after the date of submission of a pediatric assessment, FDA must make available medical, statistical, and clinical pharmacology reviews on FDA's website [FDCA § 505B(h)(1)].

Sponsors of assessments that result in labeling changes are required to distribute such information to physicians and health care providers. In addition, sponsors must submit all adverse-event reports connected to the labeling change to the Office of Pediatric Therapeutics. FDA will also make public an annual report of all such labeling changes [FDCA § 505B(f)(6)(H)].

***Other Information*** In addition to the information described above, the NDA must contain the following additional information for the drug under review:

- A full list of articles used as components
- A full statement of the composition
- A full description of the methods used in, and the facilities and controls used for, the manufacture, processing, and packing of the drug
- Samples of the drug and articles used as components, as FDA may require
- Proposed labeling

An NDA must contain a debarment certification that states that the applicant did not and will not use in any capacity the services of a person who has been debarred from such activities in connection with that application [FDCA § 306(k)(1)]. It must also contain a certification of compliance with the requirement to submit information concerning clinical trials to the director of the National Institutes of Health (NIH) for publication in the NIH clinical trial registry [FDCA § 505(b)(6)].

## 4 SECTION 505(B)(2) APPLICATIONS

A 505(b)(2) application is an NDA described in § 505(b)(2) of the FDCA. FDA guidance states that a 505(b)(2) NDA can rely on data not developed by the applicant. For example, a 505(b)(2) application can rely on FDA's finding of safety or effectiveness for another applicant's approved drug product or it can rely on published literature. The FDA's interpretation of the statute in its guidance has been controversial and has been challenged at the agency level and in court by industry—thus far unsuccessfully.

The fundamental difference between a full NDA and a 505(b)(2) application is that unlike a full NDA, a 505(b)(2) relies for approval on one or more investigations that "were not conducted by or for the applicant and for which the applicant has not obtained a right of reference or use from the person by or for whom the investigations were conducted" [FDCA § 505(b)(2)].

A 505(b)(2) application, under the statute, must contain a patent certification as to any patents listed in the NDA for the drug for which the studies relied on were performed. That certification must state that the patents have expired, that the applicant is willing to have approval delayed until they do expire, or that the patents are invalid, unenforceable, or not infringed. The applicant must notify the patent holder and the applicant for the listed drug of any claim that a patent is invalid or not infringed [FDCA § 505(b)(2)]. As discussed below with respect to ANDAs, this notification can lead to a patent infringement lawsuit, which may in turn result in a delay of up to 30 months in approval of the 505(b)(2) application.

505(b)(2) applications may not be submitted for duplicates of approved products that are eligible for approval under 505(j) [see also 21 CFR § 314.101(d)(9)]. [505(b)(2) applications may in some cases be submitted for drugs that are eligible for consideration pursuant to a suitability petition under FDCA § 505(j)(2)(C). For further explanation of suitability petitions, refer to the next section of this chapter.]

## 5 ABBREVIATED NEW DRUG APPLICATIONS (ANDAS)

Abbreviated new drug applications (ANDAs) are NDAs for generic copies of FDA-approved innovator products that are not required to contain full safety and effectiveness data, hence the term "abbreviated" [FDCA § 505(j)]. FDCA § 505(j) governs ANDAs.

### 5.1 Eligibility for ANDA Consideration

An ANDA may be filed for a generic copy of any "listed drug," that is, any drug listed in FDA's *Approved Drug Products with Therapeutic Equivalence Evaluations*

(also referred to as the Orange Book).* Listed drugs are drugs for which a new drug application has been approved for safety and effectiveness [FDCA § 505(j)(7)]. Listed drugs include those approved under an ANDA but do not include drugs that were approved under NDAs that were approved solely on safety grounds prior to 1962 and whose effectiveness has not been affirmed in the Drug Efficacy Study Implementation (DESI) process [11].

The information for each listed drug includes [FDCA § 505(j)(7)(A)]*:

- The official name
- The proprietary name
- The date of approval if the drug is approved after 1981
- The number assigned to the listed drug's NDA
- Patent information

## 5.2 Contents of an ANDA and ANDA Process

### *Equivalence or Similarity to Listed Drug*

*Bioequivalence* The essential scientific determination that must be proven in the ANDA is that the generic drug product is "bioequivalent" to the listed product [FDCA § 505(j)(2)(A)(iv)], which means that the application must contain data that show that the generic drug that is the subject of the application will produce an effect in patients equivalent to that produced by the listed drug upon which the ANDA relies [see 21 CFR § 320.1(e)]. The only exception to showing bioequivalence is in certain cases in which the ANDA is submitted pursuant to a suitability petition, which are discussed in greater detail below. For such drugs, instead of having to show bioequivalence, the statute requires that: (1) the active ingredients of the ANDA drug are "of the same pharmacological and therapeutic class as those of the listed drug"; and (2) the ANDA drug is expected to have the same therapeutic effect as the listed drug [FDCA § 505(j)(2)(A)(iv)]. FDA regulations require a showing of bioequivalence for active ingredients that are the same in the ANDA drug as in the listed drug [21 CFR § 314.94(a)(7)(ii)(B) (2007)].

There are certain circumstances in which FDA may waive the requirement for data to demonstrate bioequivalence. These are generally when, as with a solution for injection or oral administration, bioequivalence is considered to be self-evident.

*Same Active Ingredient* For listed products that contain only one active ingredient, the ANDA must show that the active ingredient of the generic product is the same as that of the listed drug [FDCA § 505(j)(2)(A)(ii)(I)]. For products with more than one active ingredient, the ANDA must usually demonstrate that all of the active ingredients are the same as those of the listed drug. In limited circumstances in which a suitability petition, as discussed below, is filed for a combination product, the ANDA must show that either all of the active ingredients are the same as those of the listed drug or that FDA has approved an ANDA may be permitted to substitute one such ingredient [FDCA § 505(j)(2)(A)(ii)(I), (II)].

*Labeling* The ANDA labeling must show that the conditions of use for the ANDA drug have been approved for the listed drug [FDCA § 505(j)(2)(A)(i)]. There is also a requirement that the ANDA labeling be the same as that of the innovator [FDCA § 505(j)(2)(A)(v)]. The only differences permitted by the statute between the ANDA drug labeling and the listed drug labeling are changes required due to differences approved under a suitability petition and different information related to the identity of a manufacturer [FDCA § 505(j)(2)(A)(v)]. There may, however, be differences reflecting the fact that the ANDA may not, because of exclusivity or patent protection, be approved for all of the conditions of use of the innovator it copies.

***Dosage Form, Strength, Route of Administration—The Role of Suitability Petitions*** Suitability petitions request permission from the FDA to file an ANDA for a drug that differs in specified ways from the listed drug upon which the ANDA would be based [FDCA § 505(j)(2)(C)]. Deviations from the listed drug may only be (1) a different active ingredient in a combination product in which the other active ingredients match those of the listed drug; (2) different route of administration; (3) a different dosage form; or (4) a different strength.

There are restrictions on a different active ingredient that can be substituted for an ingredient in a combination product subject to a suitability petition. First, the substituted active ingredient must be of the "same pharmacologic or therapeutic class as those of the listed drug" [FDCA § 505(j)(2)(A)(iv)]. Second, the substituted active ingredient in a combination product must be either an active ingredient of a listed drug or an active ingredient of a drug that is not considered a "new

*FDA's *Approved Drug Products with Therapeutic Equivalence Evaluations* is called the Orange Book because of the color of the cover of the hard-copy published versions and the color of the welcome page for the Internet edition.

*The statute also requires that FDA publish, for each drug, a statement regarding the type of bioequivalence studies required for ANDAs that refer to the listed drug. FDA apparently considers its regulations on bioequivalence requirements fulfill this obligation and does not publish a separate statement for each approved NDA.

drug" by FDA [FDCA § 505(j)(2)(A)(ii)(III)]. FDA is to grant a suitability petition only if it concludes that clinical trials are not necessary to show the safety or effectiveness of the changed product [FDCA § 505(j)(2)(C)(i)]. FDA is to act on each petition within 90 days of its submission [FDCA § 505(j)(2)(C)].

***Patent and Exclusivity Considerations*** An ANDA must include a patent certification for each patent for the listed drug that the applicant seeks to copy [FDCA § 505(j)(2)(A)(iv)]. These certifications must be one of four types or, if no patents claim the drug, FDA requests that the ANDA applicant certify that to the best if its knowledge no patents are applicable [see 21 CFR § 314.94(a)(12)(ii)]. The four types of certifications are as follows:

*Patent Information Not Filed* This type of certification states that patent information has not been filed for the listed drug [FDCA § 505(j)(2)(A)(vii)(I)]. This requirement presumes that patents exist that claim the listed drug or use of the listed drug but have not been filed. FDA recommends, but the FDCA does not require, that applicants perform a search for unlisted patents.

*Patent Has Expired or Date of Expiration* The next two types of certifications are self-explanatory. The ANDA applicant certifies that the patent on the listed drug has expired or certifies the date on which the patent will expire [FDCA § 505(j)(2)(A)(vii)(II), (III)]. The patent expiration dates are published in the Orange Book, and an ANDA with this type of certification cannot be approved until the date of patent expiration [FDCA § 505(j)(5)(B)(i), (ii)].

*Patent is Invalid, Unenforceable, or Will Not Be Infringed* The fourth type of certification must state that the patent claim on the listed drug is invalid, unenforceable, or will not be infringed by the manufacture, use, or sale of the drug covered by the ANDA [FDCA § 505(j)(2)(A)(vii)(IV)]. This type of certification must also include a statement that the ANDA applicant will provide notice to the owner (or designated representative) of the patent and to the NDA owner (or designated representative) for the listed drug. This notice must be sent within 20 days of the postmark of the notice from the applicant to FDA advising that the ANDA has been filed [FDCA § 505(j)(2)(B)(ii)(I)]. Such notice to the owner of the pioneer NDA is required even if the ANDA applicant lists a generic version of the drug.

If the patent holder commences patent litigation within 45 days after the date of notice receipt by the patent owner and the NDA holder, then the approval date of the ANDA will be delayed until a decision of the trial court finding the patent invalid, unenforceable, or not infringed, or until 30 months after the date of the notice, whichever is earlier [FDCA § 505(j)(5)(B)(iii)]. The notice must include information detailed in 21 CFR § 314.95(c). Importantly, for a patent alleged not to be infringed, the notice must contain a theory of noninfringement [21 CFR § 314.95(c)(6)(i)].

***REMS Requirements for ANDAs*** A drug that is subject to an abbreviated new drug application (ANDA) is subject to the elements of a medication guide or patient package insert for the applicable listed drug and elements to assure safe use if required for the listed drug [FDCA § 505-1(i)]. FDA may waive the requirement that the drug subject to the ANDA use the same single, shared system as the listed drug if the burden of creating a shared system outweighs its benefits or if an aspect of the elements for the listed drug is claimed by a patent and the applicant for the ANDA certifies that it has sought a license for use of an aspect of the elements but was unable to obtain one.

## 1 INTRODUCTION

Development of a therapeutic agent is a long and laborious process commencing with the discovery of a "druggable target" underlying the pathology of a disease. This finding is then exploited to identify molecules/compounds that can activate/antagonize this target. Rigorous testing for the specificity and potency of the identified agents then leads to the identification of a lead molecule/compound. The pharmacological formulation of the compound is then optimized for efficient and effective drug delivery. Initial laboratory testing is subsequently followed by detailed animal studies confirming its in vivo absorption, distribution, metabolism, elimination, efficacy, and toxicology. Following these initial laboratory observations, the drug then undergoes thorough pharmacological testing to evaluate its pharmacokinetic and pharmacodynamic properties. During this time, it may return back to the laboratory for additional modifications to modulate its half-life, solubility, bioavailability and the like. The modified agent then goes through rigorous preclinical development in good manufacturing practice (GMP)-certified laboratories, followed by studies geared to demonstrate its bioequivalency and efficacy relative to the initial molecule. The candidate agent is then carefully tested for toxicity in appropriate animal models in multiple species to define a dose that can be safely administered to human patients without adverse effects. After the successful completion of all these preclinical studies, the developer of the experimental drug typically completes an IND (investigational new drug) application to be approved for testing in human patients. After obtaining IND approval, the drug is then tested for safety and efficacy in clinical trials. Phase I clinical trials are typically dose escalation studies meant to evaluate the safety, adverse events, and maximum tolerated dose in human patients. Agents that appear to be reasonably safe then progress to phase II and eventually phase III studies to evaluate their efficacy prior to government approval and marketing. In this chapter we will discuss three recently approved agents that have been through this process and are now being tested in combination with other therapies and one experimental agent that is actively engaged in the developmental process.

## 2 BEVACIZUMAB (AVASTIN)

Bevacizumab is a humanized antivascular endothelial growth factor (VEGF) monoclonal antibody that, in combination with chemotherapy, was the first anti-angiogenic agent approved by the Food and Drug Administration (FDA) as first-line treatment for metastatic colorectal cancer. In this section we will describe the discovery of VEGF, its function and role played

in tumor angiogenesis, followed by a discussion of the preclinical and clinical studies leading to the development of bevacizumab.

### 2.1 Tumor Angiogenesis

Angiogenesis/vasculogenesis is a highly regulated process controlling the generation of new blood vessels during development, wound healing, and ovulation in adults. This process commences with increased production of angiogenic factors and a concomitant reduction in angiostatic factors. The secreted angiogenic factors then bind to and activate specific receptors on endothelial cell receptors, initiating a signaling cascade leading to increased proliferation, migration, and invasion of endothelial and/or vascular progenitor cells. The process that transforms this nascent vasculature into mature vasculature is exquisitely regulated, turning "on" and "off" discrete sets of molecular events resulting in branching, remodeling, pruning and recruitment of perivascular supporting cells [1]. Dysregulation of this process manifests itself as new vessel development in several pathological states such as diabetic retinopathy, chronic inflammatory disorders, tumor growth, and metastasis. The development of a functional vascular network is considered a critical prerequisite for the progressive growth and metastasis of neoplasms. In fact, histological examination of autopsies from patients dying of unrelated events has revealed that most of us carry in situ tumors that will not develop into disease. These observations could be interpreted to imply that dormant microscopic tumors are kept in check by the body's ability to prevent the tumors from establishing a new blood supply essential to provide them with oxygen and nutrients [2–4].

The hypothesis that antiangiogenic strategies to attack the tumor's blood supply could be exploited as an effective anticancer therapy was first postulated by Folkman in 1971 [2]. Since then several angiogenic and antiangiogenic factors involved in tumoral angiogenesis have been described, and various strategies to counter the pathways they activate are currently being investigated as potential anticancer therapies.

### 2.2 Vascular Endothelial Growth Factor

Vascular endothelial growth factor is one member of a family of growth factors that includes VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and placenta-like growth factor (PLGF) (Fig. 1). VEGF-A was the first growth factor found to have endothelial-cell-specific mitogenic properties. It was purified to homogeneity from media conditioned by bovine pituitary follicular cells as a growth factor with remarkable specificity for endothelial cells [5]. It had also been described as a vascular permeability factor (VPF), which facilitated

**Figure 1** VEGF family members (VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and PLGF) bind differentially to the VEGF receptors VEGFR-1, VEGFR-2, VEGFR-3, NRP1, or NRP2, resulting in receptor dimerization and activation. The nonsignaling NRP1 and NRP2 function by hetrodimerizing with VEGFR-2 leading to its activation. Lymphangiogenesis is initiated by VEGF-C and VEGF-D binding to VEGFR-3, leading to its homodimerization and subsequent activation.

vascular leakage into the skin [6]. Subsequent isolation and cloning of VEGF and VPF revealed them to be identical [7, 8]. VEGF is a homodimeric heparin-binding secreted protein that functions as a potent stimulator of growth and migration of vascular endothelial cells derived from arteries, veins, and even lymphatics (reviewed in [9]) (Fig. 1). VEGF-A binds and activates VEGF receptor-1 (VEGFR-1/Flt-1) and VEGF receptor 2 (VEGFR-2/KDR) expressed primarily on endothelial cells. Both VEGFR-1 and VEGFR-2 are membrane-bound tyrosine kinase receptors. VEGF binding to VEGFR-2 initiates receptor dimerization and activates a signaling cascade resulting in increased endothelial cell proliferation, while its binding to VEGFR-1 results in endothelial cell migration and differentiation (reviewed in [10]). VEGF-A plays a very significant role in embryonic vessel development wherein targeted genetic disruption of even a single allele of VEGF results in abnormal blood vessel development and lethality observed in mice [11, 12]. Decades of research have uncovered the extremely significant role played by VEGF in the regulation of both normal and pathological angiogenesis.

**Figure 2** Glioblastoma multiforme with geographic necrosis (pseudopalisading of tumor cells surrounding linear necrotic zones). Hematoxylene and Eosin images of glioblastoma specimen at 40× magnification. Areas distant from tumor vasculature (arrows) appear to be devoid of tumor cells and are referred to as hypoxic necrotic areas (arrow heads). These hypoxic necrotic areas appear to form a ring around the tumor vasculature and represent areas with poor perfusion.

### 2.3 VEGF Regulation

VEGF expression in human cancers has been shown to correlate with increased tumor vascularity and in many instances a worse prognosis. Overexpression of VEGF in human tumors promotes neovascularization and malignant growth. VEGF gene expression is rapidly induced by hypoxia and its increased expression in solid tumors is primarily a consequence of poor tissue oxygenation due to aberrant tumor vasculature. This is perhaps most apparent in pathological specimens derived from glioblastoma multiforme (GBM) grade IV malignant astrocytomas, in which areas of hypoxia/necrotic tissue are thought to be the result of poor tissue oxygenation [13] (Fig. 2). The resulting tissue hypoxia results in stabilization and activation of hypoxia inducible factor (HIF1). HIF1 is a hetrodimeric transcription factor that activates transcription of numerous hypoxia-responsive genes including VEGF [10]. Apart from increased gene expression, hypoxia-responsive 3′ untranslated region (3′UTR) in VEGF messenger ribonucleic acid (mRNA) can also function to increase its stability. Consistent with these observations, increased expression of VEGF is often observed adjacent to hypoxic necrotic areas in tissue specimens (Fig. 3). Increased VEGF in GBM often results in the appearance of hyperplastic or rapidly dividing endothelial and pericyte cell aggregates called *"glomeruloid bodies"*. These are often located in proximity to hypoxic necrotic centers within the tissue [14]. Figure 3 shows an example of a GBM specimen displaying hypoxic necrotic tissue cores and glomeruloid bodies. Hypoxia-independent activation of signaling pathways resulting from mutations in oncogene and/or tumor suppressor genes can also trigger increased levels of VEGF and subsequent angiogenesis [15]. Hence VEGF dysregulation appears to be a common factor in many different malignancies.

### 2.4 Preclinical Studies Targeting Tumor VEGF as a Therapeutic Target

Research over the last decade has established VEGF as a key endothelial-cell-specific mitogen that is essential for pathological and normal vascularization. Anti-VEGF murine monoclonal antibodies were initially generated to identify biologically relevant VEGFR-binding regions of human VEGF [16]. One of these VEGF-binding antibodies (A.4.6.1) abrogated the ability of VEGF to bind to and activate both VEGFR-1 and VEGFR-2 on endothelial cells. This murine monoclonal antibody was then evaluated for its ability to suppress angiogenesis and tumor growth in athymic mice bearing subcutaneous rhabdomyosarcoma and glioblastoma cells. The results indicated that treatment of tumor-bearing mice with A.4.6.1 inhibited tumor growth with a concurrent decrease in blood vessel density [17]. Ensuing studies using numerous human cancer cell lines confirmed the antitumorigenic potential of targeting VEGF using A.4.6.1 and other VEGF antibodies, soluble dominant negative VEGFR-2

**Figure 3** Increased VEGF in hypoxic tumor areas: (A and B): Sections derived from human glioblastoma tissue showing tumor cells adjacent to a necrotic zone (arrows) showing positive reaction with VEGF immunostain (brown staining) at low (A) and high magnification (B). The positive cells display brown cytoplasmic staining. Note the increased expression of VEGF adjacent to hypoxic necrotic areas (arrow head) in the tumor. (C and D): Hematoxin and Eosin staining of glioblastoma multiforme tissue showing microvascular proliferation at low (C) and high magnification (D). Presence of tufted aggregates of proliferating endothelial and pericytes, called glomeuloid bodies, is indicated by arrows.

receptors, small-molecule inhibitors, and anti-VEGFR-2 antibodies in vivo (Table 1) [18].

### 2.5 Pharmacological Formulation of Bevacizumab

Interfering with VEGF signaling by delivery of the murine monoclonal antibody A.4.6.1 was found to have a therapeutic advantage for anticancer therapy in many different animal models (Table 1). However, a major limitation in the use of murine monoclonal antibodies in human patients is the anti-immunoglobulin response initiated against the antibody. Humanization of monoclonal antibodies is a powerful technique used to develop antibodies that closely resemble the human IgG sequence. This technique is an effective means to avoid an antiglobulin response against itself upon administration to human patients. Antibodies are composed of two identical heavy (H) polypeptide chains and two identical light (L) chains, which are covalently bonded to each other by interchain cysteine–cysteine disulfide (S–S) linkages (Fig. 4). Humanization of the murine A.4.6.1 was achieved by transferring six complementary determining regions (CDR) from the murine A.4.6.1 into a consensus human framework, consisting of the human heavy-chain subgroup III and the light-chain subgroup κI [19]. However, simple interchange of the CDRs from murine to human antibody framework reduced the VEGF-binding affinity of the humanized antibody by more than 1350-fold as compared to the murine A.4.6.1. Seven non-CDR framework residues were then mutagenized to achieve the recombinant humanized monoclonal antibody: bevacizumab

**TABLE 1 Preclinical Studies Demonstrating Antitumor Efficacy by Targeting Tumor VEGF**

| | Preclinical Tumor Model Tested | Mechanism of VEGF Inhibition | Noteworthy Observations |
|---|---|---|---|
| 1 | Human rhabdomyosarcoma (A673), glioblastoma multiforme (G55), and leiomyosarcom (SK-LMS-1) cells implanted as subcutaneous xenograft tumors in athymic nude mice | Antihuman VEGF mouse monoclonal antibody (A.4.6.1). | Inhibition of tumor growth and vascularity in vivo [17] |
| 2 | Colon carcinoma (HM7) cells grown as experimental hepatic metastases in athymic nude mice | Antihuman VEGF mouse monoclonal Antibody (A.4.6.1). | Reduction in the number and size of hepatic metstases [157] |
| 3 | Human prostate cancer (DU145) cells grown as subcutaneous xenografts in athymic nude mice | Antihuman VEGF mouse monoclonal antibody (A.4.6.1). | Tumor growth and formation of distant metastases in lungs was suppressed [158] |
| 4 | Human fibrosarcom (HT1080) cells | Antihuman VEGF mouse monoclonal antibody (MV303). | Inhibition of primary and metastatic tumor growth in nude mice [159] |
| 5 | Human glioblastoma (C6) cells grown as subcutaneous tumors in athymic nude mice | Retrovirus encoding dominant negative mutant of VEGFR/Flk-1 (Flk-1TM) | Suppression of tumor xenograft growth [160] |
| 6 | Epidermal carcinoma (A431), colon carcinoma (Ls174T and HT-29), prostate carcinoma (PC-3, DU-145, and CWR-22) cells grown as subcutaneous tumors in mice | PTK787, a small molecule inhibitor of VEGF receptor tyrosine kinase | Suppression of tumor growth and development of distant metastases [161] |
| 7 | Breast (MDA-MB-231) Lung (Calu-3), prostate (PC-3), and ovarian (SKOV-3) tumors grown as xenografts in nude mice | ZD4190, a small-molecule inhibitor of VEGF receptor tyrosine kinase. | Significant antitumor efficacy observed in prostate and lung cancer cell line derived tumors in mice [162] |
| 8 | Human colon (SW620), lung (Calu-6), prostate (PC3), Breast (MDA-MB-231), and ovary (SKOV-3) cells grown as subcutaneous tumors in mice | AZD2171, a small-molecule inhibitor of VEGF receptor tyrosine kinase. | Significant inhibition of tumor growth observed in all tumor models [163] |
| 9 | Human epidermoid (A431), renal cell carcinoma (SK-RC-29), pancreatic (BxPC-3), or glioblastoma (GBM-18) tumors grown as subcutaneous tumors in nude mice, and Lewis lung, B16 melanoma, and 4T1 breast tumors established in C57BL/6 or BALB/c mice | Anti-VEGFR/Flt-1 mouse monoclonal antibody (DC101). | Tumor suppression observed in several mouse and human tumor models [164] |

(Avastin) (RhuMAb). Bevacizumab consisted of a sequence that was 93% homologous to human immunoglobulin (the entire framework) and 7% homologous to murine immunoglobulin (the region in A.4.6.1 that binds specifically to human VEGF). Analysis of the binding affinity kinetics of bevacizumab and A.4.6.1 revealed that both antibodies had very similar binding affinity to human VEGF. Additionally, the two antibodies were indistinguishable in their ability to antagonize VEGF bioactivity both in endothelial cell cultures (ED50s against endothelial cell proliferation were $50 \pm 5$ and $48 \pm 8$ ng/mL, respectively) in vitro and in their ability to antagonize tumor growth in vivo in mice [19]. Numerous subsequent studies further confirmed the antitumor efficacy of the humanized anti-VEGF antibody alone and in combination with other agents in mouse models of tumorigenesis (Table 2). This engineering increased the half-life of bevacizumab while maintaining its high specificity for VEGF.

For clinical studies 100 mg of RhuMAb is provided in glass vials containing histidine, trehalose, polysorbate 20, and sterile water ready for injection. The vials contain no preservative and are intended for single use. The vial is diluted into 5% dextrose ($D_5W$) prior to infusion.

### 2.6 Safety Studies

Detailed preclinical safety evaluation of bevacizumab consisted of examining tissue reactivity, investigation of its hemolytic potential and blood compatibility studies, and multiple-dose toxicity studies in adult cynomologus monkeys. Absence of nontarget tissue binding was confirmed by immunohistochemistry of tissue derived from human donors, cynomologous monkey, and rabbit tissue. No tissue cross reactivity of nontarget tissue was observed with low (10 μg/mL) or high (400 μg/mL) doses of bevacizumab [20]. The compatibility of bevacizumab with human serum was further tested by incubating

**Figure 4** Structure of an antibody: Each antibody contains two light chains (dark) and two heavy chains (light), held together by disulfide linkages (dotted lines). Each chain has a variable region and a constant region. The variable regions together constitute the antigen recognition domain within the antibody. Cleavage by papain at pH 7.0, results in the fragmentation of the antibody into two Fab fragments and one Fc fragment.

human serum with the antibody. No hemolysis, precipitation, or coagulation of human or monkey serum was observed indicating its serum/plasma compatibility [20]. Bevacizumab (0, 2, 10, and 50 mg/kg) was administered twice weekly intravenously to cynomologus monkeys for 4 or 13 weeks to determine its toxicity. Animals were monitored for weight loss, appetite, blood pressure measurements, electrocardiograms, physical activity, ophthalmic exams, and clinical pathology (hematology, clinical chemistry, and urinalysis). No bevacizumab-related clinical signs of toxicity were observed upon administration of the recombinant antibody. Bevacizumab treatment also led to inhibition of physiological angiogenesis into the growth plate and ovary and was reversible as shown by the resumption of angiogenesis when the treatment was stopped. This is consistent with its known function and was not considered an adverse event [20].

## 2.7 Clinical Studies with Bevacizumab

Based on the safety profile of bevacizumab, Genetech initiated phase I clinical trials with bevacizumab as a single agent and in combination with chemotherapy. In the first phase I study, 25 patients with metastatic cancer were given 0.1–10 mg/kg bevacizumab on days 0, 28, 35, and 42 by a 90-min intravenous infusion. Overall the infusions were well tolerated with no grade III or grade IV treatment-related adverse events [21]. Following these results several phase II studies with bevacizumab given as a single agent alone or in combination with chemotherapy were initiated [18]. A randomized phase II study comparing bevacizumab and fluorouracil (F)/leucovorin (L) with F/L treatment alone for patients with previously untreated metastatic colorectal cancer was initiated. One hundred and four patients were randomly assigned to be treated with either F/L alone (36 patients) or F/L + high-dose bevacizumab (10 mg/kg) (33 patients) or F/L + low-dose bevacizumab (5 mg/kg) [22]. Treatment with bevacizumab in combination with F/L showed an improvement in time to progression and overall survival for both the doses. Interestingly, patients treated with low-dose bevacizumab showed a better response than patients treated with the higher dose [22]. Fatal thrombosis was observed in one patient, and the lower dose was recommended for further studies in colorectal cancer patients. In a subsequent phase III trial, 813 patients were randomly segregated to receive irrinotecan, fluorouracil, and leucovorin (IFL) + bevacizumab (IFL + bevacizumab: 402 patients) or IFL + placebo (411 patients). The primary endpoint was to evaluate changes in overall survival, and the secondary endpoints were to determine if bevacizumab treatment induced progression-free survival, response rate, duration of response, safety, and quality of life. The addition of bevacizumab to IFL resulted in a statistically significant and clinically meaningful improvement in survival of patients with metastatic colorectal cancer. In 2004, administration of bevacizumab in combination with FL-based therapies was approved by the U.S. FDA for the treatment of patients with metastatic colorectal cancer. Administration of bevacizumab in combination with other chemotherapeutic drugs is being tested for efficacy as a front-line treatment for a variety of other tumor types. A recent randomized phase III study investigating bevacizumab in combination with interferon-α for patients with metastatic clear-cell renal-cell carcinoma showed improvements in progression-free survival and overall response rates [23].

## 2.8 Adverse Events Related to Bevacizumab Treatment

Hypertension was the most frequent bevacizumab-related adverse event that was noted in the studies testing combined therapy with bevacizumab + IFL in colorectal cancer patients. The underlying mechanism of hypertension is thought to be related to reduction in the levels of nitric oxide production as a consequence of VEGF blockade [24]. Other complications associated with bevacizumab treatment include gastrointestinal (GI) perforation, complications in wound healing,

**TABLE 2 Summary of Preclinical Studies for Antitumor Efficacy of the Humanized Anti-VEGF Antibody (RhuaVEGF)/ Bevacizumab**

| Agent | Tumor Type | Cell Line (Graft Location/Mouse Strain) | Dosage | Noteworthy Observation |
|---|---|---|---|---|
| *Single Agent* | | | | |
| RhuaVEGF | Androgen-independent prostate cancer | CWR223 (s.c/nude athymic BALB/c mice) | 5 mg/kg, given ip twice weekly for 4 weeks | >85% growth inhibition of established tumors with reduced MVD [165] |
| RhuaVEGF | Neuroblastoma | SK-N-AS<br>IMR-32<br>SH-SY5Y (s.c immunodeficient mice) | 5 mg/kg, given ip twice weekly once tumor volume was >0.3 mL | Significant reduction in NB tumor growth in vivo with 30–63% reduction of angiogenesis [166] |
| Bevacizumab | Non-small-cell lung cancer cells | SCH1299 (athymic nude BALB/c mice) | 100 μg/mouse ip twice weekly | Significant reduction in tumor growth [167] |
| *Combination with chemotherapy* | | | | |
| RhuaVEGF + Palcitaxel | Androgen-independent prostate cancer | CWR223 (s.c/nude athymic BALB/c mice) | RhuaVEGF: 5 mg/kg, ip twice weekly for 4 weeks, and Palcitaxel: 6.25 mg/kg s.c 5 times/week for 3 weeks | 98% growth inhibition of established tumors [165] |
| Bevacizumab + Ad-mda7 | Non-small-cell lung cancer cells | SCH1299 (athymic nude BALB/c mice) | Bevacizumab: 100 μg/mouse ip twice weekly for 4 weeks<br>Ad-mda7: $5 \times 10^9$ virus particles/dose intratumorally twice weekly for 4 weeks | Significant reduction in tumor growth, compared to Ad-mda7 treated alone or bevacizumab treated alone animals [167] |
| Bevacizumab + Ad5/3-Δ24 | Metastatic renal cancer | ACHN cells injected ip (SCID mice) | Bevacizumab: 50 μg/mouse once weekly for 5 weeks.<br>Ad5/3-Δ24: 108 virus particles once weekly for 3 weeks | No toxicity but no enhancement observed with co-treatment compared to treatment with the oncolytic adenovirus alone [168] |
| Bevacizumab + yeast-derived β-glucan | Ovarian carcinoma | SKOV-3 injected s.c (SCID mice) | Bevacizumab: 0.2 mg every third day, β-glucan: 1.2 mg every third day | Mice treated with combination had significantly smaller tumors than bevacizumab treated alone mice, and 86% of mice treated with combination were long-term survivors compared to 43% bevacizumab treated alone mice [169]. |

hemorrhage, thromboembolic events, proteinurea, and congestive heart failure. Careful monitoring and discontinuation of the drug is advised in such cases. More serious and even fatal pulmonary hemorrhage was noted in patients with non-small cell lung cancer (NSCLC) of squamous cell histology who were treated with bevacizumab [25]. Due to its impact on wound healing, bevacizumab therapy also cannot be initiated for at least 28 days before and after a surgery. Since angiogenesis during embryogenesis is essential for normal fetal development, bevacizumab is rated pregnancy category C. Due to its long half-life, patients are advised to avoid getting pregnant soon after discontinuing the drug.

## 3 PROTEASOME INHIBITORS

### 3.1 Proteasome as Therapeutic Target

The ubiquitin proteasome pathway regulates intracellular protein turnover and its function is critical to

cellular homestasis [26]. The 26s proteasome is a large multienzyme complex that functions to degrade or process intracellular proteins, including those involved in cell cycle progression and apoptosis [27, 28]. The proteasome is appreciated as playing a critical role in degrading intracellular proteins through both ubiquiti–dependent and ubiquitin-independent proteolysis [26, 29]. The proteasome consists of a 20S catalytic cylindrical complex capped at both ends by 19S regulatory subunits and is typically present within both the nucleus and cytoplasm of eukaryotic cells [30, 31]. Although other intracellular proteolytic processes are mediated by the immunoproteasome, the 26S proteasome mediates a substantial degree of protein turnover. The proteasome is central to the ubiquitin–proteasome pathway for ordered, temporal degradation of cyclins, cyclin dependent kinase (CDK) inhibitors (p21 and p27), and other proteins required for cell cycle progression in malignant cells as well as normal cells [32]. Because of its actions on cell cycle proteins, the proteasome represents a rational target for targeted therapy against neoplastic cells. Furthermore, the proteasome is known to play a role in regulation of apoptosis and/or cell survival through its effects on key mediators such as caspases, the Bcl2 family of proteins and nuclear factor κB (NF-κB) [32–34]. Based on these observations, a class of antitumor agents, termed *proteasome inhibitors* has emerged as a novel therapeutic option for the treatment of malignancies.

### 3.2 Discovery of Bortezomib as a Proteasome Inhibitor

To date, proteasome inhibitors have been separated into five classes based on their chemical structure: peptide aldehydes, peptide vinyl sulfones, peptide boronates, peptide epoxiketones, and β-lactones. The first agents to be identified as inhibitors of the proteasome were the natural inhibitor lactacystin and synthetic peptide aldehydes [27]. However, only two compounds (bortezomib/VELCADE/PS-341 and PS-519/MLN519) are currently in clinical development [27]. The latter compound, PS-519/MLN519, has been tested in healthy volunteers to determine safety, tolerability, and pharmacodynamic profiles [35]. Based on its protective ability in animal models of cerebral ischemia, it is thought that this compound may be an effective neuroprotective agent [36]. The former compound, bortezomib, has been primarily employed in the treatment of malignancy and will be the focus of the present discussion. Bortezomib is a small-molecule proteasome inhibitor (Fig. 5) developed by Millennium Pharmaceuticals, Inc., as a novel agent to treat malignancy. This drug is currently approved by the U.S. FDA for the treatment of patients

**Figure 5** Structure of bortezomib (reproduced from [171] with permission).

with multiple myeloma [37]. The rationale for developing bortezomib was that substitution of the aldehyde with boronic acid would create a compound that could form covalent and reversible complexes with the proteasome, resulting in increased potency and selectivity compared with their corresponding aldehydes [27]. As a result, a series of dipeptidyl boronic-acid proteasome inhibitors was developed and screened for activity against the standard National Cancer Institute (NCI) panel of 60 human tumor cell lines [38]. In these assays, bortezomib demonstrated effective in vitro cytotoxic activity against the tumor cell lines and was subsequently pursued in further studies for clinical development. Through its ability to inhibit the proteasome, bortezomib affects multiple signaling pathways.

### 3.3 Pharmacological Formulation of Bortezomib

Bortezomib is a modified dipeptidyl boronic acid formulated as an antineoplastic agent for intravenous injection. The chemical name for bortezomib, the monomeric boronic acid, is [(1R)-3-methyl-1-[(2S)-1-oxo-3-phenyl-2-[(pyrazinylcarbonyl) amino]propyl] amino]butyl] boronic acid. The product is provided as a mannitol boronic ester that, in reconstituted form, consists of the mannitol ester in equilibrium with its hydrolysis product, the monomeric boronic acid. The drug substance exists in its cyclic anhydride form as a trimeric boroxine. Typically, the compound is provided as a sterile lyophilized powder [Velcade (borezomib) for injection (from the package insert)].

### 3.4 Bortezomib Preclinical Studies and Mechanism of Action

Bortezomib-mediated reductions in the degradation of proteins involved in cell cycle progression and transcription factor activation leads to arrested growth of malignant cells via multiple mechanisms [33]. The first evidence that proteasome inhibition was a rational approach to cancer treatment arose from in vitro studies showing that proteasome inhibitors induced apoptosis

in leukemic cell lines, which were resistant to chemotherapy and radiation and in vivo studies using an animal model of non-Hodgkin's lymphoma [39–42]. Importantly, the apoptosis observed in these initial experiments appeared to be limited to transformed cells.

The antineoplastic effect of bortezomib likely involves several distinct mechanisms, including inhibition of cell growth and survival pathways, induction of apoptosis, and inhibited expression of genes that control cellular adhesion, migration, and angiogenesis. Thus, the mechanisms by which bortezomib elicits its antitumor activity may vary among tumor types, and the extent to which each affected pathway is critical to the inhibition of tumor growth could also differ. Bortezomib has a novel pattern of cytotoxicity against the NCI panel of 60 human tumor cell lines [33]. In addition, bortezomib has cytotoxic activity that is preferential to neoplastic cells in a variety of xenograft tumor models [32, 43, 44].

One particular pathway by which bortezomib is thought to exert its antitumor activity is via its effects on NF-κB [45]. NF-κB activity maintains cell viability through the transcription of factors that inhibit the apoptotic process induced by environmental stress and cytotoxic agents [46]. The proteasome promotes the activation of the NF-κB signaling pathway via degradation of its inhibitory protein IκB. Stabilization of IκB (e.g., by proteasome inhibition with bortezomib) and blockade of NF-κB activity renders cells more susceptible to apoptosis [38]. Reduced NF-κB activity also inhibits the expression of cell adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion protein-1 (VCAM-1), which are important for tumor metastasis and angiogenesis in vivo [27].

Despite the broad effects downstream of NF-κB, bortezomib and other proteasome inhibitors work through a number of mechanisms separate from its inhibition of NF-κB. For example, in the presence of bortezomib, cyclin and CDK inhibitor proteins required for cell cycle progression are stabilized and lead to cell cycle arrest [32]. Proteasome inhibition with bortezomib may also inhibit tumor progression via the inhibited release of pro-angiogenic factors such as VEGF and basic fibroblast growth factor (bFGF) [47]. Notably, bortezomib induces apoptosis in cells that overexpress bcl-2, a genetic trait that confers unregulated growth and resistance to conventional chemotherapeutics [34] and is believed to induce apoptosis by a p53-independent mechanism [28, 32, 38, 48]. Furthermore, bortezomib has been reported to activate both caspase-8 and caspase-9, suggesting involvement of both intrinsic and extrinsic apoptotic pathways. Notably, the mechanism of bortezomib-induced apoptosis in transformed cells appears to be highly variable, across tumor cells of different origin. For example, the differential induction of the pro-apoptotic Noxa protein has been shown to occur in melanoma cells upon exposure to bortezomib [49, 50]. Most recently, proteasome inhibition has been reported to induce endoplasmic reticulum stress and apoptosis through the unfolded protein response in human pancreatic cancer cell lines [51–53]. Together these data highlight the wide spectrum of pro-apoptotic events that are induced in response to proteasome inhibition.

### 3.5 Clinical Experience with Bortezomib

As an anticancer agent, bortezomib has shown particular promise in the setting of multiple myeloma. It has recently been approved by the FDA for patients with multiple myeloma who have received at least two prior therapies and have demonstrated disease progression on their last therapy [54]. Bortezomib is thought to be efficacious in multiple myeloma via its inhibition of NF-κB activation, its attenuation of interleukin-6 (IL-6)-mediated cell growth, a direct apoptotic effect, and possibly antiangiogenic and other effects [32]. To date, only one trial has tested bortezomib as a single agent in the treatment of metastatic melanoma and no complete or partial responses were observed [55]. However, bortezomib has shown clinical activity in other solid tumors, including renal cell carcinoma, non-small-cell lung carcinoma, androgen-independent prostate carcinoma, mantle cell lymphoma, and follicular non-Hodgkin's lymphoma [54, 56, 57].

An acceptable overall therapeutic index has been documented with bortezomib; however, there remains some risk of toxicity from this agent [37]. The most common dose-limiting side effects of bortezomib observed in phase I studies were fatigue, malaise, GI effects such as diarrhea, nausea, and loss of appetite, fluid retention, hypokalemia, hyponatremia, orthostasis, thrombocytopenia, and sensory neuropathy [58]. Subsequent clinical studies in patients with multiple myeloma have demonstrated that toxicity was observed in approximately 10% of patients receiving single agent bortezomib and that a majority of the dose-limiting toxicity associated with this drug are likely due to thrombocytopenia and neuropathy [58]. More detailed information on the pharmacokinetics and pharmacodynamics of bortezomib are beyond the scope of this review but is readily available from the product insert or the U.S. FDA [37, 58].

### 3.6 Future Studies: Combination Therapy with Bortezomib

The wide range of pro-apoptotic properties and acceptable toxicity profile of bortezomib in patients suggests

**TABLE 3 Clinical Trials Employing Bortezomib in Combination with Other Agents [170]**

| Other Agents Combined with Bortezomib | Tumor Type | Reference |
|---|---|---|
| Carboplatin | Ovarian or primary peritoneal | 59 |
| Thalidomide and dexamethasone | Multiple myeloma | 170 |
| Melphalan | Multiple myeloma | 62 |
| PEGylated liposomal doxorubicin | Multiple myeloma | 63 |
| Dexamethasone | Multiple myeloma | 65, 66 |
| Paclitaxel and carboplatin | Advanced malignancies | 67 |
| Melphalan and prednisone | Multiple myeloma | 68 |
| Docetaxel | Advanced solid tumors | 69 |
| Pegylated liposomal doxorubicin | Multiple myeloma | 70, 71 |
| Gemcitabine | Advanced solid tumors | 73 |
| Irinotecan | Advanced solid tumors | 73 |
| Gemcitabine and cisplatin | Advanced solid tumors | 74 |
| Thalidomide and dexamethasone | Multiple myeloma | 75 |

that this agent may be best utilized in combination with other anticancer therapeutics. Indeed bortezomib has been administered clinically in combination with a variety of other therapeutic agents (Table 3). A number of preclinical and clinical studies have demonstrated that bortezomib is an effective chemosensitizing agent [59–76]. Furthermore, preclinical work has demonstrated that combined treatment of malignant cells with bortezomib and receptor tyrosine kinase inhibitors, such as sorafenib, leads to enhanced apoptosis in vitro [77]. Proteasome inhibition has been recognized as an effective means for sensitizing tumor cells to tumor necrosis factor-related apoptosis-inducing ligand (TRAIL)-mediated apoptosis [78] and also appears to be a rational means of enhancing the antitumor activity of immune enhancing cytokines. Khan et al. demonstrated enhanced antitumor activity of bortezomib when administered together with interleukin-12 or interleukin-2 in murine models of neuroblastoma [79]. Other studies have demonstrated that combined administration of bortezomib and interferon-α can promote apoptosis and inhibit angiogenesis in human bladder cancer cell lines [78] and induce synergistic apoptosis in human melanoma cells [80]. Recent studies of B16 melanoma and multiple myeloma models also indicated that bortezomib may be an effective means to sensitize tumor cells to the lytic effects of dendritic cell (DC)-activated immune effector cells [81, 82]. The effects of proteasome inhibition on immune effector cells, therefore, remains an important area of investigation, as other reports have shown that proteasome inhibition can also lead to apoptosis in DC and inhibit their stimulatory capacity [83–85] and suppress $CD4^+$ T-cell function [86]. Finally, second- and third-generation proteasome inhibitors are currently under evaluation, and the available data suggests that these compounds will likely have enhanced specificity and anti-tumor properties [87, 88]. It will, therefore, be critical to evaluate the toxicity profile of these new-generation inhibitors as single agents and when given in combination with other anticancer and immune modulating therapies.

## 4 INTERFERON-A

### 4.1 History of Interferon-α (IFN-α)

The biological phenomenon known as "*interference*" was first described by Isaacs and Lindenmann in 1957 [89]. This phenomenon was defined as protection against viral infection in cells that had previously been exposed to another virus. This concept was examined because of its public health implications during a time in which there was an ongoing search for an "antiviral penicillin." In their research examining the molecular mechanisms of this phenomenon, Isaacs and Lindenmann discovered interferon (IFN) [89, 90]. Crude protein fractions, consisting of less than 1% of IFN and unsuccessfull attempts to purify and produce IFN in large quantities was a mjor limitation in the field [91]. It was not until the 1960s when IFN was recognized as a family of distinct structurally related proteins rather than a single molecule [92]. In this same decade, additional interest in the biological properties of IFN led to the discovery of its cytostatic, antitumor, and immunomodulatory properties [92, 93]. IFN research was later advanced by the work leading to its purification to homogeneity in solution. This facilitated production of the cytokine in sufficient amounts to study its physicochemical properties [94] and later for the cloning of the first IFN gene [95]. Competition between the pharmaceutical industry and academic research eventually led to the production of IFN for use in patients, and this substance was one of the first natural proteins to become available for the clinical treatment of malignancies [96]. Human IFNs are a heterogenous family of proteins that function endogenously to protect the host from viral infection. Type I IFN genes are clustered on human chromosome 9p21 [97] and mediate their biological effects through a common receptor, IFN-αβR, which is ubiquitously expressed throughout the body. The IFN gene family consists of 13 IFN-α members, a single member each of IFN-β, IFN-κ, IFN-ω, and IFN-ε [98–100]. Despite the large number of endogenously produced IFNs, IFN-α is the subtype that is used

most frequently in clinical medicine and, therefore, will remain the focus of the present chapter.

### 4.2 Pharmacologic Formulation of IFN-α

Interferon-α is available from two commercial sources. Either Roferon-A (Interferon-alfa-2a, recombinant; Roche, Inc.) or INTRON-A (Interferon-alpha-2b; Schering-Plough, Inc.). Both formulations are manufactured by recombinant deoxyribonucleic acid (DNA) technology that employs a genetically engineered *Escherichia coli* bacterium containing DNA that encodes for either the human inteterferon-α-2a or interferon-α-2b protein (165 amino acids; molecular weight =19,000 Da). Fermentation is carried out in a defined nutrient medium containing the antibiotic tetracycline hydrochloride; however, the presence of the antibiotic is undetectable in the final, purified product. Roferon-A is supplied both as an injectable solution in a vial or a prefilled syringe. Roferon-A formulations typically contain Interferon-alpha-2a ranging from 3 to 36 million international units (IU), and contain polysorbate 80, benzyl alcohol, and ammonium acetate as a preservative. Intron-A is supplied as a sterile lyophilized powder for reconstitution and injection, which is formulated with glycine, sodium phosphate dibasic, sodium phosphate monobasic, and human albumin. Intron-A is also supplied in solution for injection or as a multidose pen for injection. These formulations contain sodium chloride, sodium phosphate dibasic, sodium phosphate monobasic, edentate disodium, polysorbate 80, and *m*-cresol as a preservative.

### 4.3 Clinical Experience with IFN-α as a Treatment for Malignancy

Cytokine therapy with IFN-α is regularly used as a treatment for metastatic melanoma and renal cell carcinoma. IFN-α is also FDA-approved for melanoma patients as an adjuvant following the surgical resection of thick primary tumors and dissection of regional lymph nodes [101–103]. Historically this cytokine has also been used to treat chronic myelogenous leukemia and Kaposi's sarcoma [104, 105]. The recombinant form of this cytokine became available for use in human clinical trials during the 1980s [106]. In the setting of metastatic melanoma, the response rate to IFN-α typically ranges from 10 to 20%, where, in general, complete responses represent one-third of total responses [108, 109]. Likewise, a 15% objective response rate and a significantly prolonged overall survival of patients with metastatic renal cell carcinoma (RCC) was observed in response to single-agent IFN-α in randomized clinical trials [110, 111]. Subsequently, a series of clinical trials evaluated the use of IFN-α in the adjuvant setting for melanoma patients who underwent complete surgical resection of their tumor but were at high risk for recurrent disease. An initial phase III trial was conducted in which patients were randomized to receive either high-dose IFN-α (20 MU/m$^2$/d intravenously) for 1 month followed by 10 MU/m$^2$/thrice weekly subcutaneously or observation [112]. The results of this trial indicated an increase in both the overall and relapse-free survival of IFN-α-treated patients [112]. Subsequent trials of high-dose and low-dose IFN-α regimens (3 MU thrice weekly for 2 years) also demonstrated an increase in relapse-free survival of high-dose IFN-α-treated patients. However, these studies did not report a difference in overall survival in a similar population of surgically treated patients. Despite these conflicting results, an adjuvant trial comparing an antiganglioside vaccine to high-dose IFN-α was stopped as the result of an early analysis that showed a clear survival benefit to patients in the IFN-α arm [103]. Overall, IFN-α remains the only FDA-approved adjuvant therapy for patients with melanoma who have undergone surgical resection of high-risk lesions. There remains no alternative therapy that has shown efficacy in randomized trials in this setting, and IFN-α will likely continue as the standard of care in the adjuvant setting and will continue to be given in combination with other therapeutic agents. Accordingly, there remains a need to identify relevant biomarkers that might be useful for predicting clinical response or toxicity in response to this therapy.

### 4.4 Dosage and Toxicity Considerations

As with many other cytokine therapies, the use of IFN-α is tolerated quite well by many patients but results in a marked degree of toxicity in others. Particularly when given at high-doses, IFN-α is associated with a unique spectrum of toxicities that often limit patient compliance and have tempered enthusiasm for using this therapy as a first-line agent for metastatic disease [113]. The most common adverse reactions to high-dose IFN-α are flulike symptoms including fever, fatigue, headache, myalgias, chills, and arthralgias. In some cases, IFN-α treatment may result in depression; therefore, IFN-α is not recommended in patients with a pre-existing psychiatric condition. Gastrointestinal effects, mild proteinuria, intermittent or transient skin rashes, and myelosuppression are also commonly seen. Hepatic toxicity is manifested primarily as liver enzyme disturbances, which are generally mild to moderate and transient. Pulmonary complications are relatively unusual and may include dyspnea, cough, or more rarely pneumonitis or pneumonia. Edema, hypotension, arrhythmia, and tachycardia have been observed and

**Figure 6** Mechanism of interferon-α antitumor action. The molecular targets critical for the antitumor properties of IFN-α have not been precisely defined. However, IFN-α is known to act directly on the tumor cell, on the microenvironment, and via its ability to stimulate the host immune system.

may be related in some cases to the febrile reaction that occurs frequently during initial therapy. IFN-α could potentially lead to a depression of the hepatic clearance of certain drugs that use the hepatic microsomal cytochrome P-450 pathway [113].

In contrast, lower or moderate doses of this cytokine are often well tolerated and in rare cases can be administered in a sustained manner for several months or even years [101, 114]. The dosages employed in early phase I and phase II trials ranged from 3 to 100 MU per square meter ($m^2$) and would be considered very high dose regimens according to the current guidelines. The route of IFN-α administration does not appear to be a critical factor influencing clinical response. Indeed, investigators have reported complete clinical responses following both intravenous (i.v.) or intramuscular (i.m.) routes of administration in sequential clinical trials conducted at the same institution [108]. Despite this variability in dosage and in subject populations of the early trials, the response rates ranged between 5 and 30%. Although complete clinical responses have been observed most frequently upon the administration of higher doses (10–50 MU/$m^2$), complete responses have been shown to occur in response to very low doses of IFN-α (1–3 MU/$m^2$) [108, 113]. Recent data have also demonstrated that escalating clinical doses of IFN-α are no more effective at initiating signal transduction and gene expression in immune effector cells [115, 116]. Indeed, recent experience with tumor-targeted antibodies or other biologic agents demonstrate that higher doses do not necessarily exert the optimal biologic effect. These data are intriguing in that they suggest elevated doses of cytokines associated with greater toxicity may not necessarily be producing a greater clinical benefit. Therefore, it remains of value to explore strategies to individualize dosing of IFN-α and other immunotherapeutic cytokines on a patient-by-patient basis.

### 4.5 Mechanism of Action

The precise mechanism by which IFN-α mediates its antitumor activity remains undefined. Because IFN-α can bind to its receptor present upon both tumor cells and host cells, this cytokine can mediate pleiotropic effects in a biological system (Fig. 6). Indeed, in vitro studies have demonstrated that treatment of tumor cells with IFN-α leads to decreased cell proliferation and in some cases can promote apoptosis or programmed cell death [117–119]. Thus, the direct actions of IFN-α on the tumor cell were thought to constitute a major mechanism of action. Furthermore, other studies have confirmed a role for IFN-α in inhibiting the secretion of pro-angiogenic molecules from tumor cells (e.g., basic fibroblast growth factor) [120, 121] and upregulating the expression of major histocompatibility complex class I (MHC class I) proteins on tumor cells [122, 123].

Despite the apparent direct effects of IFN-α on the tumor cell, Belardelli and Gresser have conducted numerous eloquent studies investigating the mechanisms of antitumor effects of type I IFN in mice transplanted with Friend leukemia cells (FLC) [92, 124–129]. These tumor cells express Friend leukemia virus antigens on the cell surface and are metastatic to the liver and spleen following injection into syngeneic DBA/2 mice. Belardelli and Gresser demonstrated that IFN-α induced antitumor activity in mice transplanted with an IFN-resistant FLC clone. From these and subsequent studies [125, 130, 131], it was demonstrated that IFN-α acted to elicit antitumor activity through host-dependent mechanisms.

A series of more recent studies have further dissected the mechanism of host-dependent, IFN-α-mediated antitumor activity in murine models of melanoma. We found that the antitumor effects of IFN-α were dependent upon signal transducer and activator of transcription-1 (STAT1)-mediated signal transduction in the host immune cells, rather than the tumor cell [132, 133]. Subsequent studies have further demonstrated that exogenous IFN-α has profound antitumor activity when administered to mice lacking the negative regulatory suppressor of cytokine signaling-1 (SOCS1) protein (an inhibitor of STAT1 signal transduction) [134]. This finding is particularly intriguing as it suggests that modulating the negative regulators of IFN-α-induced signal transduction might be a means of sensitizing a cell to enhanced effects of IFN-α.

Clinical studies have shown that infiltration of $CD8^+$ T cells in cutaneous lesions from melanoma patients was associated with a favorable clinical response to IFN-α therapy [135]. Finally, studies indicate that melanoma patients who develop autoantibodies and clinical manifestations of autoimmunity during the course of adjuvant IFN-α therapy are less likely to experience disease recurrence. In a report by Gogas et al., autoantibodies were detected in 26% of melanoma patients following adjuvant IFN-α therapy ($n = 52$ patients total). Univariate and multivariate regression analyses indicated that autoimmunity was an independent prognostic marker for improved relapse-free survival and overall survival [136]. The development of autoimmunity may signify that exogenous IFN-α can break the tolerance of host T lymphocytes to host antigens as well as melanoma-associated antigens and further suggests that a principal mechanism of its antitumor action is immunologic in nature.

### 4.6 Future Studies with IFN-α

The extensive clinical experience with IFN-α and the fact that it can bind to receptors on both host immune effectors and tumor cells makes it an attractive candidate for combination therapy. Over the last several years, IFN-α has been administered in combination with multiple chemotherapeutic agents, cytokines, or tumor-targeting antibodies [23, 137–139]. In addition, more stable, PEGylated forms (PEG-INTRON) of IFN-α have become available for clinical use [140]. It is thought that this formulation might potentially allow for prolonged stability of the drug in vivo and fewer toxic side effects. As with most other cytokines, there remains a critical need to identify the molecular determinants that differentiate optimal dosing, patient toxicity, and clinical responsiveness to this drug. Advances in our mechanistic understanding in these areas could lead to important improvements in choosing which patients may be most likely to gain benefit from this potentially toxic therapy and to identify rational combinations for clinical use.

**Figure 7** Mechanism of anticancer effect of oncolytic viral therapy: Step 1: Initial infection of neoplastic tissue by oncolytic virus (OV) causes infection of both cancer cells and tumor associated normal fibroblasts and stromal cells. Step 2: The conditionally replication-competent virus is able to replicate only in the permissive cancer cells and proliferating tumor endothelium. Viral particles that infect normal cells are unable to replicate in the nonpermissive environment and are eventually cleared. Step 3: Tumor-specific replication of the oncolytic virus leads to lytic destruction of the infected cancer cells and the tumor supporting vasculature.

## 5 ONCOLYTIC VIRUS

Oncolytic virus (OV) is a biological cancer therapy based on the natural or engineered propensity of some viruses to replicate in and destroy cancer cells (Fig. 7). While the concept of using live viruses to infect and destroy tumors dates back nearly/over a century, advances in molecular biology and virology have accelerated the development of OV in the last two decades [141]. Therapeutic viruses used for the treatment of cancer can broadly be classified as replication-deficient and conditionally replication-competent viruses. Replication-deficient viruses are mostly used as gene therapy vehicles to deliver a therapeutic or cytotoxic gene to the cancer cells. Conditionally, replication-competent viruses are viruses whose replication potential is compromised in normal cells but can manipulate the aberrant molecular/genetic pathways in tumors to replicate efficiently in cancer cells. This leads to the lytic destruction of the infected malignant cell. Oncolytic viruses currently being tested for safety and efficacy include herpes simplex virus (HSV), and adenovirus, and RNA viruses such as Newcastle disease virus (NDV), measles virus, vaccinia virus (VV), and vesicular stomatitis virus (VSV). In this section we will describe the conception and testing of oncolytic viruses derived by genetically manipulating wild-type HSV-1-derived viruses.

### 5.1 Oncolytic Viruses Derived from Herpes Simplex Virus-1

HSV-1 is an enveloped, double-stranded DNA virus containing a large, well-characterized, fully sequenced

**Figure 8** Structure of the HSV-1 wild-type genome and some of the oncolytic viruses generated from it. (1) The HSV-1 genome consists of a linear double-stranded DNA of about 152 kb, encoding for more than 80 genes. Four inverted repeat sequences: Terminal repeat long ($TR_L$), terminal repeat small ($TR_S$), internal repeat long ($IR_L$), and internal repeat small ($IR_S$) divide the genome into unique long ($U_L$) and a unique small ($U_S$) segment. The three origins of replication within the HSV genome are indicated by circles. Locations of genes that are disrupted/deleted for the creation of tumor-specific replication competent viruses are indicated. (2) dlsptk is generated by a 360-bp deletion within the locus $U_L23$, encoding for viral HSVTK. (3) hrR3 is generated by an in-frame gene disrupting insertion of the *E. coli β-galactosidase* gene into the $U_L39$ locus encoding for large subunit of viral ribonucleotide reductase. (4) NV1716 is generated by deletion of both copies of the gene encoding for ICP34.5 within the terminal repeat sequences of the HSV genome.

genome of about 152 kb of DNA that encodes for more than 80 genes (Fig. 8). While the large size makes genetic manipulations cumbersome, it also provides ample opportunities to remove genes that are not essential for replication (estimated to be about 30 kb). These genes can be replaced to allow for the insertion of therapeutic transgenes within the viral backbone. Furthermore, the ability of HSV-1 to remain as an episome avoids the possibility of any insertional mutagenesis of the infected cell. These properties make HSV-1 a very desirable vector for therapeutic applications. In addition, HSV is sensitive to several antiherpetic drugs such as acyclovir (ACV) and gancyclovir (GCV), which are readily available to keep viral replication in check if needed. Together these factors make HSV an excellent candidate for oncolytic therapy.

### 5.2 HSVTK-Deleted Oncolytic Virus

HSV thymidine kinase (HSVTK) is a homidimeric protein encoded by $U_L23$ (ICP36) gene of the HSV genome. Unlike its mammalian counterpart, the viral enzyme has a very broad substrate specificity, permitting it to phosphorylate pyrimidine and purine nucleosides along with several nucleoside analog molecules. Viral HSVTK is required for nucleotide metabolism essential for DNA replication and in nondividing cells that do not express the mammalian counterpart of this enzyme. Based on these observations was born the hypothesis that an HSV virus deficient in HSVTK activity would be restricted for its replication in dividing cells, and this could be exploited for the generation of an oncolytic HSV. Subsequently, the first genetically altered HSV was created by a 360-bp (base pair) deletion within the viral gene infected cell protein 36 (ICP36) encoding for the enzyme thymidine kinase (HSVTK) [142] (Fig. 7). This mutant HSV (dlsptk) was tested for oncolytic efficacy in human glioblastoma cell lines and cultures in vitro. Furthermore, dlsptk treatment of human gliomas implanted into immune-deficient mice showed that treated tumors were smaller and mice survived longer than untreated mice with gliomas [142]. Further analysis of the pathogenesis of corneal infection of severe combined immunodeficiency (SCID) mice by dlsptk revealed persistent infection, which resulted in death of inoculated mice within $80.2 \pm 21.3$ days. The lack of sensitivity of dlsptk to commonly used antiherpetic drugs such as ACV and GCV (which exploit the virus-expressed HSVTK), combined with its neurovirulence precluded the use of this virus in human patients. However, the efficacy seen in preclinical animal models underscored the need for the development of safer oncolytic HSV vectors, which retain the antiherpetic drug-sensitizing HSVTK gene and are also less virulent.

### 5.3 Ribonucleotide Reductase-Deficient OV

Ribonucleotide reductase (RR) is required for the de novo synthesis of deoxyribonucleotides and is essential for viral DNA synthesis and replication. HSV-1 encodes for its own RR, composed of a large and small subunit encoded by $U_L39$ and $U_L40$, respectively. The proteins encoded by $U_L39$ and $U_L40$ together make up an $\alpha2\beta2$ tetramer constituting the functional RR. Like the HSVTK, viral RR is essential for viral replication in nondividing cells. However, the cellular enzyme compensates for this defect in cycling cells. Hence, an HSV lacking its own RR would be replication competent only in mitotic cancer cells but not in nonreplicating normal cells. To test this hypothesis a mutant virus, deficient for the large subunit of RR (ICP6/RR) was created by the insertion of an *E. coli LacZ* gene within the $U_L39$ gene locus [143] (Fig. 7). Cytopathic and drug sensitivity assays using this attenuated virus (hrR3) revealed efficient cancer cell killing in vitro and also efficient tumor killing in animal models of tumorigenesis [144, 145]. Figure 7 shows the destruction of brain tumors in rat with brain tumors treated with hrR3. Additionally, drug sensitivity assays revealed that the attenuated hrR3 was 10-fold more sensitive to antiherpetic drug GCV. HSVTK results in phosphorylation of GCV to a toxic nucleotide precursor, which results in death of infected cells and also uninfected bystander cells. This suggested that hrR3-infected glioma cells would be sensitive to killing by GCV. Consistent with this treatment of rats bearing intracranial tumors with GCV in combination with hrR3 significantly enhanced the antitumor effect of hrR3 [146]. More recent evidence also indicates that RR mutant HSV may be "molecularly targeted" to replicate more efficiently in cells with specific oncogenic mutations such as homozygous deletion of the *p16* gene [147].

### 5.4 ICP34.5-Deficient Oncolytic HSV

Interferon-induced, double-stranded RNA-activated protein kinase (PKR) is one of the principal cellular defenses against viral infection. Cellular PKR is maintained at low levels in uninfected cells but is induced by interferon. Activated PKR phosphorylates $\alpha$ subunit of eIF-2$\alpha$ leading to a total shutoff of host protein synthesis. HSV gene $R_L$-1 encodes for ICP34.5 protein, which binds to protein phosphatase 1$\alpha$ and leads to the dephosphorylation of $\alpha$ subunit of eIF-2$\alpha$. HSV-1 ICP34.5 was identified to be the neurovirulence gene and attenuation of both the copies of this gene led to

reduction of neurovirulence associated with HSV-1 in vitro and in vivo [148, 149]. More significantly this mutant virus retained the ability to replicate in actively dividing mouse embryo cells but not in confluent mouse embryo cultures [149]. Consistent with these results an RL-1 null HSV-1 mutant (1716), which fails to produce ICP34.5 was able to efficiently replicate in and cause subsequent cell death in a majority of glioma cell lines and primary tumor-derived cells [150] (Fig. 8). The in vivo antitumor efficacy of 1716 was tested in mice bearing experimental brain tumors, and treatment resulted in a statistically significant increase in survival [151, 152]. Pathological examination of mice injected intracranially with 1716, revealed a finite, self-limiting host response to 1716, highlighting the potential of using it for therapeutic purposes.

### 5.5 Pharmacological Formulation

The clinical-grade HSV 1716 used in human trials was prepared by amplifying low-passage laboratory stocks in BHK-21/C13 cells from a master seed cell bank under cGMP conditions (by Q-One Biotech Ltd., Glasgow, UK). The amplified clinical grade viral stocks were tested for contamination and evaluated for titers and stored at –70°C. The virus was stored at the appropriate dilution in 1 mL of human serum albumin, (0.5–1.0%) in isotonic phosphate-buffered saline (PBS). The titers of the virus were reconfirmed a week prior to the injection date. All studies were approved by the UK gene therapy advisory committee.

### 5.6 Clinical Testing in Human Patients

***HSV Mutant 1716*** Based on its safety profile in animals the mutated HSV 1716 was tested in UK for safety in human patients with malignant brain tumors [153]. This clinical study represented the first foray of inoculating mutated oncolytic HSV vectors into the brains of human patients with malignant brain tumors, and for concerns of safety, only a very moderate dosage of the virus was permitted to be tested. In this study, nine patients with malignant glioma were treated with doses of $10^3$, $10^4$, and $10^5$ plaque forming units (pfu) of HSV 1716 by direct intratumoral injection. All the patients were diagnosed with recurrent malignant glioma (eight glioblastoma and one anaplastic astrocytoma) that had relapsed following radical treatment, including surgery and radiation therapy. Patients were closely monitored and no adverse clinical events that could be attributed to the administration of 1716 were observed. No evidence of encephalitis or ongoing lytic replication was found in any treated patient. Buccal sawbs and serum samples from patients were examined weekly for presence of HSV, and no evidence of viral shedding or reactivation of endogenous latent virus was seen in any patient [153]. Five of these nine patients underwent a subsequent tumor progression, and biopsy samples from these patients showed no signs of 1716 or wild-type HSV by polymerase chain reaction (PCR) [153]. No evidence of efficacy was observed with inoculation of this dosage in patients, nevertheless the absence of any significant toxicity that could be attributed the administered OV was encouraging and subsequently two clinical trials to test therapeutic efficacy of HSV mutant 1716 were initiated. In a subsequent report by the investigators, it was noted that two of these nine patients were alive and stable at 4 years and 4 months and 3 years and 7 months after treatment [154].

Next, the therapeutic potential of HSV 1716 was also assessed in 5 patients with metastatic melanoma. In each patient paired distinct nodules were injected with either dilutent or $10^3$ pfu of HSV 1716. The very low dosage given in the first clinical study was based on the hypothesis that the oncolytic virus should be able to replicate and hence produce a higher dose within the tumor. In the second clinical study evidence of viral replication in human high-grade glioma was examined. Twelve patients with high-grade malignant glioma received $10^5$ pfu of HSV mutant 1716 by direct intratumoral stereotactic injection [155]. Tumor resection was carried out 4–9 days after treatment, and the tissue was examined for the presence of HSV DNA by PCR, Southern blotting immunohistochemistry, and the presence of infectious viral particles by plaque assay. Results from plaque assays revealed the presence of infectious viral particles in resected tumors from 2 out of 12 patients. Southern blot analysis confirmed that the recovered virus was HSV mutant 1716. HSV DNA was detected by PCR at the site of injection in 10 out of the 12 patients, and specimens from distal tumor sites of only 4 patients were found to be positive for HSV DNA [155]. Immunohistochemistry of tissue samples revealed positive staining for HSV proteins in tumor tissues from 2 of the 12 patients. The absence of detectable viral DNA protein or infectious particles in some specimens could be attributed to tissue sampling errors owing to nonuniform spread of the injected virus throughout the tumor tissue, or simply reflect the need to improve current methods used for detection. Nevertheless, the study demonstrated evidence of HSV presence in tissue without any obvious signs of toxicity [155].

Based on these studies, another clinical trial in the UK was initiated to test the therapeutic efficacy of the HSV mutant 1716 in human glioma patients. Despite the lack of toxicity seen in those trials, due to paramount safety concerns the therapeutic dose given to the patients was not increased as would have been done for clinical trials with a chemotherapeutic agent. A total of 12 patients who had been diagnosed with high-grade

recurrent (6 patients) or newly diagnosed (6 patients) glioma underwent gross tumor resection. After the initial tumor debulking, $10^5$ pfu of HSV mutant 1716 was injected into 8–10 sites within the tissue surrounding tumor cavity. The patients were carefully monitored with a comprehensive clinical work-up including immunological, hematological (full blood count with white cell count differential), biochemical (urea, electrolytes, liver function tests, and bone profile), and neurological examinations. The lack of any virus-related toxicity in this study considerably strengthened the safety profile of this approach even though the virus had been injected into tissue involving functioning brain. The expected median survival for patients with GBM is one year from the time of initial diagnosis and only 3–6 months following diagnosis of a recurrent tumor. One patient with a recurrent tumor and two patients diagnosed with primary GBM survived for more than 22, 18, and 15 months, respectively. The patient who survived for more than 22 months was diagnosed with a recurrent tumor but was disease free at 22 months. However, a causal relationship between response and viral treatment could not be established. This study demonstrated that HSV 1716 can be injected into the normal brain of individuals without any ensuing toxicity.

### 5.7 Future of HSV1716

HSV1716 is currently being pursued by Crusade Laboratories (Glasgow, UK). The company has been granted orphan drug status in Europe for "the use of HSV mutant 1716 in the treatment of glioma. The company has received regulatory approvals to initiate a phase III trial for glioma patients. Glioma patients with a first recurrence after surgery will be randomized into one of two treatment arms: HSV1716 or conventional chemotherapy. Satisfactory results in this trial could lead to a license and marketing authorization in glioma. The company is also pursuing phase I/II safety and biological activity studies in patients with ovarian carcinoma and unresectable hepatocellular carcinoma.

### 5.8 Second-Generation Multimutated Oncolytic Viruses: G207

In parallel with the HSV mutant 1716 studies going on in the UK, a doubly attenuated oncolytic HSV has also been investigated in clinics in the United States. Owing to the overriding concerns of safety arising from the use of singly mutated viruses, oncolytic viruses with multiple genetic defects were created for the treatment of cancer. G207 is one such virus that has deletions at both gamma 34.5 (RL1) loci and an in-frame and gene-disrupting insertion of *E. Coli* β-galactosidase gene within the ICP6 gene ($U_L39$), making it replication competent in dividing cells. This minimizes the chances of G207 reverting to wild type and maintains an attenuated neurovirulence, temperature sensitivity, as well as ganciclovir hypersensitivity [156]. The insertion of β-galactosidase permits easy detection of cells harboring the virus in infected tissue. Preclinical testing of this virus was performed in nude mice harboring subcutaneous or intracerebral gliomas. Intraneoplastic administration of the virus resulted in slower tumor growth and/or prolonged survival [156].

Preclinical toxicity studies of G207 also found it to be avirulent upon intracerebral inoculation of mice and HSV-sensitive nonhuman primates. Shedding and biodistribution of G207 was determined in New World owl monkeys (*Aotus nancymae*) after intracerebral inoculation of $3 \times 107$ pfu of clinical-grade virus. Even after 2 years of inoculation G207 DNA was found to be restricted to the brain, although no infectious viral particles were obtained. Histopathology of the necrospied tissue revealed normal brain even at the site of injection. Absence of virus DNA in tears, saliva, and vaginal secretions indicated lack of viral shedding and suggested that strict biohazard management of G207 patients may not be required. Together these results implicate the possibility of considering mutimutated oncolytic viruses such as G207 for clinical evaluation for the treatment of cancer.

Safety of intracerebral inoculation of G207 in humans was determined in a dose escalation study in patients suffering from recurrent malignant glioma. The protocol was approved by the recombinat DNA advisory committee of the National Institutes of Health and the Food and Drug Administration. The trial was initiated with the administration of $1 \times 10^6$ pfu of G207 into the brains of three patients posttumor resection. After 28 days of observation to confirm lack of acute toxicity, three patients were then recruited into the next cohort and were treated with the higher dosage. In the last cohort the patients were treated with $1 \times 10^9$ p.f.u of G207 inoculated into five sites after surgical resection of the brain tumor. No toxicity that could be directly attributed to the infectious virus was noted in this study. This study suggested that G207 can be safely inoculated into human brain tumors up to doses of $1 \times 10^9$ pfu without any adverse events. This agent is currently being investigated for efficacy in clinical trials. Future studies will reveal the efficacy of combining oncolytic viruses with radiation and chemotherapy in patients.

# DEVELOPMENT OF COUNTERMEASURES FOR BIOTERRORISM IN THE UNITED STATES

Gregory H. Levine and Jeffrey L. Handwerker
*Ropes and Gray LLP, Washington, D.C.*

## 1 INTRODUCTION

Shortly after the terrorist attacks of September 11, 2001, 22 people contracted anthrax infections from *Bacillus anthracis* spores deliberately disseminated through the U.S. postal system. Five of them died [1]. The anthrax killings, together with terrorist groups' demonstrated intention to inflict catastrophic casualties on civilian populations, focused the attention of the U.S. public, lawmakers, and government officials on the acute dangers of bioterrorism.

Bioterrorism presents unique threats to the security of the United States and other nations. Attacks involving contagious biological weapons, in particular, pose a risk of widespread disease outbreak. Such attacks can mimic naturally occurring disease, potentially delaying recognition and response [2].* In addition, once a terrorist has the capability of producing a biological weapon, there are few if any limits on the quantity of that weapon the terrorist can produce. In the right environment, a pathogenic microbe can reproduce on its own. This characteristic distinguishes biological weapons from other weapons that terrorists might use to cause mass casualties, such as chemical, nuclear, and radiological weapons, which are limited by the availability and cost of critical production materials and equipment [3].

Biological weapons also present unique challenges due to their ability to evade countermeasures, either through natural alteration or genetic manipulation. Recent advances in biotechnology and the life sciences, including the spread of expertise needed to create modified or novel organisms, have the potential to expand the spectrum of biological agents that might be used as weapons (HSPD 10). In 2000, for example, Australian scientists inadvertently discovered that introducing the interleukin-4 gene into an *ectromelia* virus (the cause of mousepox) suppressed primary antiviral immune responses in recently immunized genetically resistant mice [4]. Others have shown that it is possible to create strains of *B. anthracis* that are resistant to powerful antibiotics, including fluoroquinolones and macrolides [5]. These and other findings suggest that the bioterror threat will require increasingly sophisticated responses over time.

This chapter focuses on one element of biodefense—the development of medical countermeasures to be used in advance of, or in response to, a bioterrorist attack. Unlike other areas of medicine, for which private market forces are generally sufficient to spur private industry to develop and market useful products, there are few market incentives to develop and market vaccines, diagnostics, and therapeutics for biodefense purposes. To the contrary, the disincentives to such investment in the absence of government intervention far exceed the incentives. First, the market for biodefense products is unpredictable. Even assuming that a manufacturer could find a buyer for a biodefense countermeasure, the product may be stockpiled but never used, and the demand for the product ultimately will

*Homeland Security Presidential Directive 10 will be hereafter appear as HSPD 10.

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*

depend on whether biological attacks occur or are expected to occur. The market demand is, therefore, not amenable to the return-on-investment analysis upon which pharmaceutical and biotechnology companies typically make business decisions [6]. Second, the market is not likely to offer attractive profit margins. Biotechnology and pharmaceutical companies anticipate operating margins far higher than those achieved by traditional defense contractors [6]. Third, industry has perceived biodefense products as posing disproportionate product liability risks, largely as a consequence of the unfamiliarity of the exposure and the manufacturer's lack of control over how government agencies deploy the countermeasure [7].

Since 9/11, Congress has enacted various federal laws to address the insufficiency of traditional market forces and to foster private industry's involvement in developing biodefense countermeasures, as well as countermeasures for naturally occurring pathogens that also can be used for bioterror ends. These laws focus on creating so-called push-and-pull incentives, with countermeasure-related research grants (primarily through the National Institutes of Health) providing the push with research grants and regulatory streamlining and countermeasure procurement programs providing the pull [8]. Most notably for pull mechanisms, the Project Bioshield Act of 2004 created a $5.6 billion fund for the purchase of biodefense countermeasures. Along with these incentives, various measures have been adopted to reduce the regulatory burdens on companies willing to invest in the biodefense space.

The majority of this chapter discusses the laws, regulations, and actions taken to date in the United States to spur the development of diagnostic, prophylactic, and therapeutic agents for biodefense. Initial efforts to encourage the development of such products have been slow to bear fruit and have been beset by well-publicized setbacks, such as the cancellation of a $877 million Project Bioshield contract with VaxGen Corporation to produce a new-generation anthrax vaccine. These setbacks have led to calls in some circles for further action to spur research and development in the biodefense field.

Although the measures described in this chapter generally reflect regulatory retrenchment intended to encourage research and development activities, the U.S. government also has concerns about research materials with potential bioterror uses falling into terrorists hands, and in particular the risk that more widespread participation in biodefense research will increase the opportunities for such diversion. Consequently, a number of laws and regulations intended to prevent such occurrences have been adopted or tightened since 9/11. Because any person entering into research or development in this field must be aware of these regulatory restrictions, the last section of this chapter briefly describes the most important of these restrictions, including select agent restrictions, biosafety laboratories, and export controls.

## 2 INCENTIVES TO CONDUCT RESEARCH AND DEVELOPMENT (R&D) OF BIOTERRORISM COUNTERMEASURES

Increased research funding, primarily through the National Institute of Allergy and Infectious Disease (NIAID) within the National Institutes of Health (NIH) is the primary push tool the U.S. government has employed in an attempt to encourage biodefense R&D. The government has also attempted to develop a pull incentive by streamlining and accelerating the regulatory pathway for biodefense products. This section describes the efforts of Congress and the executive branch of the government in these areas.

### 2.1 Research Incentives

Congress responded to the 9/11 and anthrax attacks by increasing funding earmarked for civilian biodefense research. From a negligible amount in fiscal year (FY) 2001, Congress appropriated $3.2 billion in FY 2002, and steadily increased the amount through FY 2005, when biodefense research spending peaked at $7.6 billion. Though funding has declined since FY 2005, it remains substantial and well ahead of pre-2001 levels [9]. The effect has been the dedication of billions of federal dollars allocated to a research enterprise that was essentially nonexistent before 2001.

The lead grant-making body for civilian biodefense is the NIAID. The NIAID's biodefense research priorities, which cover basic and translational research to foster the development of diagnostics, therapeutics, and vaccines, are based largely on categories established by the Centers for Disease Control and Prevention (CDC), as modified by NIAID [10]. The CDC's list of biologic agents is prioritized into three categories (categories A, B, and C, with category A representing the highest priority threats) based on their potential public health impact, potential for dissemination, and special needs for effective public health intervention. Examples of CDC categories A, B, and C agents are shown below listed in Table 1.

NIAID produces a regularly updated Funding Opportunities List that lists Requests for Applications (RFAs), which are NIAID-sponsored initiatives to stimulate targeted research by requesting grant applications in a well-defined scientific area [11]. NIAID also pub-

**TABLE 1 CDC Pathogen Categories**

| Category A | Category B | Category C |
|---|---|---|
| Anthrax (*B. anthracis*)<br>Botulism (*Clostridium botulinum* toxin)<br>Plague (*Y. pestis*)<br>Smallpox (variola major)<br>Tularemia (*Francisella tularensis*)<br>Viral hemorrhagic fevers (e.g., Ebola, Marburg) | Ricin toxin<br>Staphylococcal enterotoxin B<br>Typhus fever<br>Viral encephalitis<br>Food safety threats (e.g., *Salmonella*, *Escherichia coli*, *Shigella*)<br>Water safety threats (e.g., *Vibrio cholerae*) | Emerging infectious diseases such as Nipah virus and hantavirus |

lishes Requests for Proposals (RFPs), which are initiatives sponsored by NIAID that request proposals for a contract to meet a specific need, such as the development of an animal model [12].

All applications for funding must either have direct approval of the director of NIAID or be in response to an RFA or RFP [13]. Requirements for funding applications vary according to the RFP or RFA. As an example, the RFP for biodefense vaccines for categories A and B pathogens requires a demonstration of safety and proof-of-concept efficacy in an animal model and a well-defined and feasible product development plan for advancing the vaccine candidate to achieve certain specified objectives [14].

Funding applications are reviewed and accepted within about 6 months of receipt of the application. Peer reviewers are assigned applications within the first 6 weeks. The applications are given a priority score, with some receiving an expedited second level of review and others deferred for another few months. Once a second review is accepted, NIAID's main advisory council must approve funding. After approval, funding is paid out within 1 or 2 months. Even for the deferred applications, the approval process takes less than a year [15].

Outside of NIH, funding may be available through the Department of Defense (DoD) and other federal agencies. For example, in FY 2006, the DoD's Chemical and Biological Defense Program budget dedicated to basic and applied research was more than $332 million [16]. These agencies issue solicitations for projects on the federal business opportunities website (http://www.fedbizopps.gov).

## 2.2 Regulatory Pathway Incentives

Regulatory barriers present unique challenges in the biodefense field. Classic scientific techniques for drug development, which normally involve large clinical studies of a drug's effectiveness in patients with the target disease, will not usually be ethical or feasible for countermeasures to bioweapons. Nor does the typical 10-year pathway to develop a new drug in response to a pathogen fit well in a world characterized by rapidly mutating and possibly intentionally engineered threats [17].

Lawmakers and regulators have undertaken a number of initiatives to address some of these burdens, primarily focusing on regulation of new products by the Food and Drug Administration (FDA). FDA's dual mission of protecting the public health by ensuring the safety and effectiveness of medical products, while simultaneously promoting the public health by "promptly and efficiently" reviewing clinical research and acting upon marketing applications, routinely confronts the agency with difficult, high-stakes challenges [18]. If the agency permits the marketing of a product that later turns out to be unsafe, it is criticized as being too lax. If the agency delays or blocks the marketing of a product by demanding adherence to a high standard of scientific proof, the agency is often criticized as depriving patients of the ability to avail themselves of potentially beneficial therapies. This dilemma is even more stark in the area of biodefense, where it is often difficult or impossible to develop the type of clinical evidence the agency would normally require. This section describes measures FDA has taken to address this challenge, as well as other steps it has taken to encourage the development of medical countermeasures.

***Animal Rule and Development of Animal Models***

Generally, FDA requires manufacturers of new drugs and biologics to establish the safety and effectiveness of their products in one or more pivotal clinical trials. For biodefense countermeasures, however, such studies may be impossible because one cannot ethically expose healthy research subjects to potentially lethal bioterrorist agents. The challenge, therefore, is to develop a standard of proof that sufficiently protects the public health while still permitting approval of important biodefense countermeasures.

To its credit, FDA began considering this issue several years before 2001. In July 1997, the agency published a Request for Comments in which it asked what evidence of efficacy, other than that from human trials, would be appropriate to demonstrate the safety and efficacy of products that may provide protection against toxic chemical, biological, radiological, or nuclear substances [19].* After receiving responses, on October 5, 1999, FDA published a proposed rule under which it would

*Reference 19 will hereafter appear as # Proposed Rule.

grant marketing approval for a new drug or biological product on the basis of adequate and well-controlled trials in animals when it is "scientifically reasonable to expect that the effect of the drug or biological product in animals is reasonably likely to predict clinical benefit in humans" [19, at 53964]. This rule would apply only to drug or biological products for which "[d]efinitive human efficacy studies cannot be conducted because it would be unethical to deliberately expose healthy human volunteers to a lethal or permanently disabling toxic biological, chemical, radiological, or nuclear substance without a proven treatment; and field trials to study the product's efficacy after an accidental or hostile exposure are not feasible" [19, at 53968].

Further, under the proposed rule of October 1999, FDA would rely on evidence from studies in animals only where:

- There is a reasonably well understood pathophysiological mechanism of the toxicity of the substance and its prevention or substantial reduction by the product.
- The effect is independently substantiated in multiple animal species.
- The animal study endpoint is clearly related to the desired benefit in humans.
- The data or information on the kinetics and pharmacodynamics of the product or other relevant data or information allows selection of an effective dose in humans [19, at 53968].

The proposed rule also outlined requirements for post-marketing studies, approval with restrictions to assure safe use, and information necessary to distribute to patients and potential patients [19, at 53968]. In addition, the proposed rule allowed for expedited withdrawal of the approval if the product was later shown to be unsafe, to have no clinical benefit under its intended conditions of use, or if its safe use cannot be ensured by restricted distribution [19, at 53970].

At the time of the anthrax attacks in the fall of 2001, FDA had not issued the final animal rule. Consequently, in one of the first significant post-9/11 laws, commonly known as the Bioterrorism Act of 2002, Congress instructed the Secretary of Health and Human Services (HHS) to complete the process of rulemaking that was commenced with the October 1999 proposed rule by promulgating a final rule [20].*

FDA issued the final rule in May 2002 [21].† While the proposed rule would have required such substantiation of a product's effectiveness in more than one animal species, the final rule provides that the effect must be demonstrated in more than one animal species "unless the effect is demonstrated in a single animal species that represents a sufficiently well-characterized animal model for predicting the response in humans" [22]. FDA implemented this change because the multiple-species requirement may be inappropriate or unnecessary in certain situations [23]. One such circumstance is when only one species is capable of reacting with a response predictive for humans, such as when there is only one nonhuman host for the targeted microorganism [23]. Another may be when particular species are specifically well recognized as predictors of effectiveness in humans [23]. Therefore, single-species efficacy studies will generally be limited to situations where the study model is sufficiently well recognized so as to render studies in multiple species unnecessary. It is anticipated that single-species efficacy studies will most often be done for anti-infective drug products because the pathophysiological mechanisms of infectious diseases are usually well understood, and animal models for infectious diseases have been studied for years and are well characterized [23].

A product approved through the animal rule must be tested for safety in human clinical trials in accordance with existing requirements. The animal rule relaxes the normal evidentiary burden only with regard to effectiveness, for the simple reason that safety studies, unlike effectiveness studies, require exposure only to the experimental product, not to the toxic agent the countermeasure is intended to counteract.

FDA issued its first approval under the so-called Animal Efficacy Rule in February 2003. The approved drug, pyridostigmine bromide, increases survival after exposure to Soman nerve gas poisoning [24]. Despite its limited use to date, the Animal Efficacy Rule has potential applicability to a broad variety of agents, including anthrax, smallpox, botulism, plague, tularemia, and others. At the time of this writing, trade press reports indicated that one company was planning to seek FDA approval under the animal rule for its novel respiratory antibiotic shown to be protective against a lethal dose of inhalation anthrax when tested in primates [25].

To encourage the development of countermeasures under the animal rule, FDA has led or participated in efforts to foster discussion and consensus on appropriate animal models for effectiveness testing. Even before the animal rule was finalized, FDA and NIH hosted a workshop titled Anthrax Vaccine: Efficacy Testing and Surrogate Markers of Immunity [26]. That workshop focused on the substantial effect of the disease in multiple animal species, the degree of similarity to the human disease, and whether the immune response in the animal resembles the human immune response [26].

*Reference 20 will hereafter appear as Bioterrorism Act.
†Reference 21 will hereafter appear as Final Rule.

In October 2004, FDA's Center for Biologics and Evaluation, the NIAID, and the HHS Office of Research Development and Coordination convened a public workshop on Animal Models and Correlates of Protection for Plague Vaccines [27]. One purpose of this session was to discuss human disease and relevant animal models, including what constitutes good animal models for plague and whether there is sufficient understanding of the pathophysiology of the plague to qualify it under the animal rule. The FDA also announced that it would hold a workshop in November 2007 titled Anthrax Vaccines; Bridging Correlates of Protection in Animals to Immunogenicity in Humans to discuss possible strategies for bridging animal efficacy data to human immunogenicity data for investigational anthrax vaccines [28]. Despite these early efforts, much more scientific work needs to be done toward the development of acceptable animal models before the animal rule can be utilized to its full potential.

***Emergency Use Authorization*** Recognizing that approved countermeasures might not be available at the time of a terrorist attack, Congress included in the Project Bioshield Act of 2004 a new streamlined Emergency Use Authorization (EUA) process by which FDA can authorize the distribution of bioterrorism countermeasures on an emergency basis [29]. Under the EUA authority, FDA may authorize the use of an unapproved medical product or an unapproved use of an approved medical product during a "declared emergency involving a heightened risk of attack on the public or U.S. military forces" [30].

In the absence of such an emergency authorization procedure, a drug or biological product that has potential utility as a countermeasure, but that is not approved for such a use, could be distributed from a stockpile for countermeasure use only pursuant to an Investigational New Drug (IND) application. FDA's IND regulations, however, require ongoing institutional review board oversight over clinical research, detailed research protocols, signed informed consent of all study subjects, reporting of trial-related adverse events within specified time frames, and the like (21 CFR Part 312). Such requirements are generally incompatible with the distribution of a countermeasure in an emergency, as the military learned in trying to distribute anthrax vaccine to the armed forces under an IND at the start of the Iraq war [31]. By substituting for full marketing approval, the EUA permits the distribution of an unapproved countermeasure without complying with the IND regulations.

Before an EUA may be issued, the Secretary of HHS must declare an emergency. Such an emergency declaration must be based on: (1) a determination by the Secretary of Homeland Security that there is a domestic emergency, or the potential for a domestic emergency, involving a heightened risk of attack with a specified biological, chemical, radiological, or nuclear agent or agents; (2) a determination by the Secretary of Defense that there is a military emergency, or a significant potential for a military emergency, involving a heightened risk to U.S. military forces of attack with a specified biological, chemical, radiological, or nuclear agent or agents; or (3) a determination by the Secretary of HHS of a public health emergency that affects or may affect national security and that involves a specified biological, chemical, radiological, or nuclear agent or agents [32]. Once a declaration is in effect, the Secretary of HHS may issue an EUA if, after consulting with the directors the NIH and the CDC, the Secretary concludes that:

- The agent in question can in fact cause a serious or life-threatening disease or condition.
- It is reasonable to believe that the product for which emergency use is requested may be effective in diagnosing, treating, or preventing the disease or condition.
- The known and potential benefits of the product outweigh the known and potential risks of the product.
- There is no adequate, approved, and available alternative to the product [21 USC § 360bbb-3(c)].

An EUA terminates either when the circumstances necessitating the emergency cease to exist or one year from the date of the authorization, whichever is earlier [21 USC § 360bbb-3(b)(2)]. The Secretary may, at his or her discretion, renew the authorization. The Secretary also must promptly publish a notice of each authorization and termination or revocation of each authorization, along with an explanation of reasons for the action, in the *Federal Register* [21 USC § 360bbb-3(h)].

The first and, to date, only use of EUA authority was in 2005, involving Anthrax Vaccine Adsorbed (AVA) for the prevention of inhalation anthrax in military personnel.* Although AVA had been licensed since 1970, it was not originally contemplated as a biowarfare or bioterrorism countermeasure, and some members of the Armed Forces objected to the DoD mandatory Anthrax Vaccine Immunization Program (AVIP). In March 2003, six plaintiffs filed suit in the U.S. District Court for the

*Although FDA has worked with CDC to identify potential medical countermeasures in the Strategic National Stockpile as candidates for EUA for an unapproved use, there have been no authorizations apart from AVA.

District of Columbia seeking an injunction against AVIP and a declaration of AVA as an investigational drug when used for protection against inhalation anthrax [33]. The court declared that using AVA for inhalation anthrax constituted an unapproved use of an approved product and required a public notice and comment period before FDA could issue a determination that the AVA license included use for prevention of inhalation anthrax [34]. The DoD and FDA responded by issuing an EUA for the use of AVA to prevent inhalation anthrax for individuals between 18 and 65 years of age deemed by the DoD to be at heightened risk of exposure due to attack with anthrax (70 *Fed Reg* 5453). Not surprisingly, this issuance of the EUA for AVA proved controversial on Capitol Hill [35]. Before the issue could ultimately be resolved, however, FDA issued a final notice finding AVA safe for prevention of inhalation anthrax, thus eliminating the need for an EUA [36].

***Priority Review, Accelerated Approval, and Fast Track*** Beginning in the 1980s, in response to demands of acquired immunodeficiency syndrome (AIDS) and cancer patients, FDA began developing programs intended to accelerate access to drugs and medical devices intended to treat serious and life-threatening diseases. In the drug area, current programs that are potentially available to developers of biodefense products include:

- Priority Review, an FDA designation for drugs and biologicals that offer a major advance in current treatment or provide a treatment where no satisfactory therapy currently exists. Priority Review moves a product's application for marketing approval up in the FDA review queue and subjects it to a shorter (6-month) target review timeline under the Prescription Drug User Fee Act (PDUFA) [37].
- Accelerated Approval of drugs and biologicals intended to treat serious or life-threatening illnesses that provide meaningful therapeutic benefit to patients over existing treatments. FDA Accelerated Approval regulation—often referred to as the Subpart H regulation—provides for approval based on a surrogate endpoint of clinical benefit (21 CFR § 314.500).
- Fast Track treatment for new drugs intended to treat serious or life-threatening conditions and that demonstrate the potential to address unmet medical needs. FDA's Fast Track program, in addition to Priority Review and Accelerated Approval, include FDA review of portions of a new drug application before the entire application is complete, as well as close consultation and collaboration with the agency throughout the development process [38].

In the Bioterrorism Act of 2002, Congress expressly authorized the Secretary of HHS to designate certain bioterrorism countermeasures as "fast track" products [39]. The Bioterrorism Act also provided that drugs submitted for approval under the Animal Efficacy Rule may be designated as fast track products [39 at § 122(b)]. While this statutory provision did not confer any meaningful new authority or requirements upon FDA, it provided a clear signal of Congress's desire for FDA to give developers of biodefense products extra support, assistance, and high-priority treatment.

***Orphan Drug Designations*** The Orphan Drug Act, initially signed into law in 1983, offers various incentives to potential product sponsors, including tax incentives, grants for clinical research, and 7 years of marketing exclusivity if a product that FDA designates as an orphan drug or biological obtains FDA approval for the orphan use [40]. Orphan drugs are products intended to treat rare diseases, defined by statute as diseases affecting fewer than 200,000 Americans [FFDCA § 526(a)(2); 21 USC § 360bb(a)(2)]. As with medical countermeasures for bioterrorism generally, the fear regarding the orphan drug market is that there is not enough of a profit incentive to drive production without legislative or regulatory remedies. Orphan drug exclusivity, in particular, is a powerful incentive. Unlike other forms of nonpatent exclusivity under the Federal Food, Drug, and Cosmetic Act (FFDCA), orphan drug exclusivity blocks FDA approval not only of so-called abbreviated new drug applications, which do not require original safety and effectiveness data, but also full new drug applications (NDAs) containing original clinical data [FFDCA § 527(a); 21 USC 360cc(a)]. The only way to break orphan drug exclusivity is to prove that a subsequent version of the drug is clinically superior or that the holder of the orphan drug approval cannot supply enough product to meet market demand [21 CFR §§ 316.3(b)(13), 316.25(a)(3), 316.36].

One might expect many bioterrorism countermeasures not to qualify for orphan drug status, in that they would be used in a large number of people in the event of a bioterrorist attack. Certain other countermeasures, however, may be expected to have more limited use and therefore can qualify for orphan drug status. Indeed, FDA has approved several orphan drugs for countermeasure uses. The first such products were pentetate calcium trisodium injection (Ca-DTPA) and pentetate zinc trisodium injection (Zn-DTPA), approved for marketing in August 2004 [41]. Both drugs treat radioactive

contamination from materials such as plutonium, americium, or curium. FDA also granted approval to vaccinia immune globulin intravenous (VIGIV) as an orphan drug in February 2005 [42]. VIGIV, a specialty antibody made from human plasma, was approved for treating and preventing severe reactions, such as a severe infection of the skin, that may be brought on by administration of the smallpox vaccine [43]. The drug was developed by DynPort Vaccine Company LLC in partnership with the U.S. Department of Defense Joint Vaccine Acquisition Program for use as a biological defense vaccine [44].

Given the general tendency toward regulatory flexibility to encourage biodefense countermeasures, product developers should consider whether their products might qualify for orphan treatment. One possible objective measure of the potential market size for a countermeasure might be number of doses or courses of therapy the government has indicated it is seeking to procure for the Strategic National Stockpile, if such information is available. The operation of the Project Bioshield program, which governs the procurement of countermeasures for the Strategic National Stockpile, is discussed below.

## 3 ADVANCED DEVELOPMENT, PRODUCT PROCUREMENT, AND MARKETING

New attention to the need for medical countermeasures also has had a widespread effect on how the government has chosen to organize itself and do business with pharmaceutical and biotechnology companies developing countermeasures. As noted, the Project Bioshield Act is the primary pull incentive for development of biodefense countermeasures. The Weapons of Mass Destruction Medical Countermeasures (WMD MCM) Subcommittee, a subset of the Committee on Homeland and National Security of the National Science and Technology Council (NSTC) that predated the Project Bioshield Act [45], has been designated as the lead agency responsible for Project Bioshield implementation and policy planning [46].*

In 2006, the HHS established the Public Health and Emergency Medical Countermeasures Enterprise (PHEMCE) to implement the administration's strategy for development and procurement of medical countermeasures to bioterrorist threats. Although intended to replace the WMD MCM Subcommittee for implementation of Project Bioshield, the WMD MCM Subcommittee has in fact survived the establishment of the PHEMCE and continues to work under the NSTC. Later in 2006, President Bush signed into law the Pandemic and All-Hazards Preparedness Act (PAHPA), which, among other things, established the Biomedical Advanced Research and Development Authority (BARDA). BARDA will eventually assume oversight of the PHEMCE. Questions remain after this reshuffling about how the interagency community will coordinate its efforts and whether authorities have been clearly delegated and delineated.

Despite the lack of clarity regarding interagency oversight, Project Bioshield and other related legislation have focused on providing incentives to the private sector to aid the government in establishing a strategic national stockpile of medical countermeasures. The Project Bioshield Act created this new market. After some criticism regarding government oversight, unanticipated complications in the market and poor incentive programs, follow-on legislation has attempted to fill in those gaps. Major focuses of subsequent legislation were the funding gap created by the push-and-pull system, intellectual property ownership, and liability protection.

### 3.1 Project Bioshield: Procuring a National Stockpile of Medical Countermeasures

***The Project Bioshield Act of 2004*** The Project Bioshield Act of 2004 [47] was designed to address the lack of a commercial market for research, development, and deployment of medical countermeasures against biological, chemical, radiological, and nuclear weapons. It created incentives for private firms to invest in such countermeasures using three separate policy devices. First, it authorized an appropriation of $5.6 billion for procurement with the aim of creating a Strategic National Stockpile of medical countermeasures by the year 2013. The act also directed the NIH to use expedited and simplified peer review and contracting procedures for bioterrorism-related research and development. Finally, the Bioshield Act empowered FDA to use emergency use authority as discussed in Section 2.2.

The central feature of the Project Bioshield Act is the creation of a $5.6 billion reserve fund for the procurement of medical countermeasures against the use of biological, chemical, radiological, and nuclear weapons. This fund permits the federal government to contract for the purchase of medical countermeasures in advance of full product development and FDA approval. Such advance contracting is intended to provide incentives for private companies to initiate research and development of medical countermeasures.

Procurements for the Strategic National Stockpile require interagency collaboration and several determinations. First, the Secretary of the Department of

*Reference 46 will hereafter appear as BioShield CRS Report.

Homeland Security (DHS) must determine what chemical, biological, radiological, and nuclear agents present a "material threat." If a countermeasure for such a threat is not currently available, the secretaries of DHS and HHS can submit a joint proposal to the president to develop that countermeasure. The secretaries must also determine that the countermeasure is a "specific security countermeasure," that is, that it is specifically appropriate for inclusion in the Strategic National Stockpile. Payments made from the $5.6 billion reserve fund must await presidential approval. To date, HHS has obligated about $1.5 billion of the $5.6 billion national stockpile procurement fund (Table 2).

In April 2007, HHS published its plan for implementing the PHEMCE for chemical, biological, radiological, and nuclear threats [48]. The PHEMCE plan contained a list of threats and medical countermeasures that will become the principal procurement priorities under Project Bioshield [48]. The threats on which PHEMCE will focus are, among others, anthrax, botulism, hemorrhagic fever (filoviruses, e.g., Ebola and Marburg), tularemia radiological/nuclear agents, typhus, smallpox (variola virus), volatile nerve agents, and the plague [48, at 10]. The projected future top-priority medical countermeasure programs for PHEMCE include, for example, anthrax antitoxins, anthrax vaccine, acute radiation sickness medical countermeasures, broad-spectrum antibiotics and antivirals, diagnostics, smallpox antivirals, smallpox vaccine, and a volatile nerve agent single antidote [48, at 13]. Of those medical countermeasures, in the next 2 years, PHEMCE hopes to procure broad-spectrum antibiotics, anthrax vaccines, smallpox vaccines, and acute radiation sickness medical countermeasures [48]. Countermeasure procurements for threats posed by the various forms of influenza are not addressed in the PHEMCE implementation plan because HHS has issued a comprehensive HHS Pandemic Influenza Plan [48, at 2]. The HHS Pandemic Influenza Plan has its own provisions about procurement and stockpiling of antivirals and vaccines that target influenza specifically [49].

***Challenges and Criticism for Project Bioshield*** Project Bioshield was enacted with the implicit assumption that its financial incentives would entice large pharmaceutical companies to participate in the development of medical countermeasures. That assumption has not proven correct. As a result, HHS has turned to smaller biotechnology companies. Those companies may, however, lack the capital to implement and sustain a successful research and development program. The cancellation of the large contract with VaxGen for the anthrax rPA vaccine, for instance, has sparked concern within industry regarding the detrimental effects that the HHS contract decision-making process and bureaucratic delay can have on smaller companies. Some companies have also expressed doubt about HHS's ability to manage Bioshield contracts in an effective manner [50].

In its 2007 report on Project BioShield, the Congressional Research Service (CRS) observed that the process for developing countermeasures was moving too slowly [51]. According to CRS, DHS's process for determining material threats is lagging. Meanwhile, HHS has not contracted for medical countermeasures associated with existing material threats. The majority of the funding obligated for stockpile procurement, which began in 2004, has not yet resulted in products moving in substantial volumes into the stockpile.

On September 10, 2007, seven members of Congress wrote the Secretary of HHS, Michael O. Leavitt, to express their frustration with the delays in implementa-

**TABLE 2 Project Bioshield Contract Awards**

| Material Threat | Product | Company | Cost ($ millions) |
|---|---|---|---|
| Anthrax | rPA vaccine | VaxGen, Inc. | 877.5 (Cancelled) |
| Anthrax | AVA vaccine | Emergent BioSolutions | 242.7 |
| Anthrax | ABthrax | Humane Genome Sciences | 165.2 |
| Anthrax | Anthrax immune globulin | Cangene Corp. | 143.8 |

| Smallpox | Vaccinia Ankara (MVA) smallpox vaccine | Bavarian Nordic A/S | 500.0 |
| | | | Total Cost: |
| | | | 2,331.2 million |
| | | | –877.5 million |
| | | | **$1,453.7 million** |

*Sources*: Adapted from ref. [46], at 11, and Department of Health and Human Services, News Release: HHS Buys Next Generation Smallpox Vaccine, June 4, 2007. Available at: http://www.hhs.gov/news/press/2007pres/06/pr20070604a.html.

tion of Bioshield. They cited companies who asserted that "the Department's inability to effectively manage contracts have [sic] caused them to reconsider participating in Project Bioshield" [52]. Congress hoped that some of their organizational solutions to the above problems would also alleviate bureaucratic delay and increase transparency. Hearings on Capitol Hill have continued to highlight congressional attention to these issues and the belief of members of Congress that Project Bioshield implementation has not been as efficient as they would have hoped [53].

In 2005, the Senate considered a proposed BioShield II bill [54], aimed at addressing the major criticisms and gaps created by the Project Bioshield Act. The key observation of the Senate was that the private sector lacked adequate incentives to invest in medical countermeasures. Among other things, the bill would have established a new procurement fund under the auspices of DHS. The bill also attempted to improve procurement procedures by streamlining the process, requiring and encouraging regulatory improvements and naming DHS as the lead agency. In addition to new funding, other enticements for businesses included new research and development tax incentives and grants and an antitrust exemption for certain activities. The bill attempted to resolve major concerns about intellectual property incentives and product liability protection as well. Although the bill died on the Senate floor, it provided a roadmap for areas of improvement on the Project Bioshield Act. Since then, Congress has passed some new laws to remedy obvious problems and help accelerate procurement processes. Nevertheless, it is clear that criticisms regarding pace and transparency will remain.

### 3.2 Medical Countermeasures Deemed Commercial Items: Contracting Flexibility

The Homeland Security Act of 2002, which established the DHS, provided "special streamlined acquisition authority" for DHS designed to improve incentives for commercial companies to invest in bioterrorism research and to streamline the procurement process [55]. Specifically, section 883 of the Act empowered the Secretary of Homeland Security to deem a DHS procurement to be a "commercial item" procurement if the Secretary "determines in writing that the mission of the Department . . . would be seriously impaired without the use of such authorities" [55, at § 833(a)].

This "deemed commercial item procurement" authority substantially increased DHS's authority in contracting because commercial item procurements are substantially more streamlined than traditional government procurement processes. For example, commercial item procurements are: excepted from certain intellectual property provisions that apply to traditional government contracts [56], exempt from many socioeconomic provisions, such as affirmative action [56, at 52.212-4], permitted to use commercial financing procedures [56, at 12.210], simplified in terms of the contract requirements [56, at 12.403] and more flexible in terms of negotiation [56, at 12.302].

To date, DHS has not exercised its § 833 authority to deem an otherwise noncommercial item contract as a commercial item procurement [57]. DHS officials recently informed the Government Accountability Office (GAO) that the authority to deem a procurement a "commercial item" was "not worth the time and effort required to justify their use given the relatively modest increase in flexibility" [57]. On September 30, 2007, § 833 thus expired without action from Congress. Accordingly, homeland security contractors must comply fully with the requirements imposed on traditional government contractors.

### 3.3 Creation of BARDA and Filling the Valley of Death Funding Gap

One measure to address at least some of the Project Bioshield inadequacies was the Pandemic and All-Hazards Preparedness Act (PAHPA), passed in December 2006, which created the Biomedical Advanced Research and Development Authority (BARDA) [58]. A central purpose of the bill was to allow medical countermeasure makers to receive earlier payments for their medicines. The small biotechnology companies who were participating in Project Bioshield often lacked the capital to fund advanced research and development programs. Because of this capital deficit, the funding gap between the initial grant and the projected procurement, nicknamed the "valley of death," was a serious impediment for those smaller companies.

BARDA is the new Project Bioshield manager and will also oversee PHEMCE research, development, and procurement. It is the lead agency for all advanced development and procurement of medical countermeasures for biological, chemical, radiological, and nuclear threats, as well as emerging infectious diseases. BARDA specifically noted in its draft strategy plan that it was created in part to address the valley of death by supporting products with funding before they are ready for procurement [59]. The FY 2008 budget allocates $189 million toward that goal [60]. PAHPA endows BARDA with the authority to pay countermeasure manufacturers "an advance payment, partial payment for significant milestones, or payment to increase manufacturing capacity" on the authority of the Secretary of HHS as necessary to ensure success of their projects, thus helping to fill the funding gap [61]. Therefore, medical

countermeasures in theory will be more mature when they become subjects of Project Bioshield procurements, significantly lessening the risk involved in their procurement as well [62]. In addition, BARDA has authority to fund advanced development of medical countermeasures that are not eligible for the national stockpile under Project Bioshield [63]. BARDA also aims to incorporate and execute the HHS Pandemic Influenza Plan and the PHEMCE implementation plan, which prioritized pathogens and countermeasures for funding and procurement, into its strategy.

### 3.4 Addressing Intellectual Property Questions

Certain special rules regarding defense and homeland security procurements allow companies greater flexibility in negotiating contracts with the government than most government contractors would face. For example, the Homeland Security Act (HSA) of 2002 [64] and the PAHPA provide DHS and BARDA, respectively, with so-called other transaction authority. Other transactions are transactions that are not constrained by the same rigid procurement rules and regulations that contractors would normally face under the Federal Acquisition Regulations and the Bayh–Dole Act of 1980. The Federal Acquisition Regulations provide numerous contracting requirements, including competition, pricing, and cost accounting standards that generally must be satisfied. In the area of medical countermeasures, many of these requirements would be onerous and some of the competition provisions may even be unfeasible. The Bayh–Dole Act (35 USC § 200–212) generally governs the allocation of rights in patentable inventions first conceived or reduced to practice under federally funded agreements (such as procurement contracts, grants, or cooperative agreements) and grants the government a nonexclusive license to use the invention for governmental purposes.

Other transaction (OT) authority was first developed for the Defense Advanced Research Projects Agency (DARPA) in the 1980s. It was then extended to other parts of the Department of Defense. In general, there are two types of OTs: research OTs and prototype OTs. To be categorized as a research OT, DoD must establish the following three criteria:

- It is not "feasible or appropriate" to use a standard contract, grant, or agreement to carry out the project. A company's reluctance to contract under the intellectual property rules of the Bayh-–Dole Act will satisfy this condition.
- The research project does not duplicate other DoD research.
- To the extent practicable, the contractor must contribute at least half the funding for the project (10 USC § 2371).

DoD contracts for prototype OTs must comply with three conditions as well:

- The research does not duplicate other DoD research.
- To the maximum extent practicable DoD must use competitive procedures.
- The contractor must pay at least one-third of the cost of the project, subject to a few exceptions (10 USC § 23.71 note).

The HSA extended DoD's OT authority to DHS through a 5-year pilot program (6 USC § 391). The three requirements for research OTs are the same for DHS as for DoD. DHS must satisfy additional criteria before implementing a prototype OT. In addition to the three requirements on DoD prototype OT contracts, DHS requires that any contract valued at more than $5 million must include a clause permitting the GAO to examine the contractor's books and records. The wording of the HSA is unclear, but it may also require that the Secretary of DHS determine that it is not "feasible or appropriate" to use a standard procurement contract, grant, or agreement for the project. DHS's pilot program for OT authority expired at the beginning of 2008 and was subsequently extended.

The PAHPA, which in 2006 established BARDA, also granted BARDA OT authority but did not expand that authority to any other part of HHS. Section 401 of PAHPA also cited to 10 USC §2371, DoD's OT authority statute, to establish BARDA's OT authority. PAHPA specifies that OT authority for BARDA should be exercised for research or prototype OT contracts in accordance with the then existing DOD rules for prototype OTs. The senior procurement executive for HHS must sign off on any other transaction valued at more than $20 million dollars.

OT authority does not extend to any agency outside of DHS and DoD other than BARDA. Although the Project Bioshield Act provides some guidance on procurement generally, it does not specifically address OT authority, nor does it have protections for companies with intellectual property concerns. As mentioned above, the Project Bioshield Act does contain expedited procurement authority and creates some exceptions to the standard procurement rules. For instance, the act allows "other than full and open competition" and expedited peer review. For procurement for the national stockpile itself, the act requires certain contract terms

to be included in the procurement contract. Those specified terms address payment, contract duration, storage of the medical countermeasure, product approval, and export controls. However, important industry concerns about liability were also not addressed.

### 3.5 Liability Protection

One of the greatest concerns for potential Project Bioshield participants has been the risk of legal liability involving medical countermeasures. Were a biological terrorist attack to occur, it is likely that hundreds or even thousands of Americans would require medical countermeasures. In the unfortunate event that a medical countermeasure did not protect against the biological threat, or if it had an unanticipated side effect, the company that developed and manufactured the drug would theoretically be exposed to potentially ruinous liability. Such risks present major disincentives for companies, who have already displayed skepticism about the risk of failure and low profit margins that characterize the medical countermeasures industry.

A variety of laws limit liability exposure for drug companies interested in producing medical countermeasures. The most significant is the Pandemic Readiness and Emergency Preparedness (PREP) Act, which provides extensive liability protection, but thus far has been applied only to the avian flu vaccine [65]. Other relevant laws include the Support Anti-terrorism by Fostering Effective Technologies (SAFETY) Act [66] and some disease-specific legislation.

***P.L. 85-804: The Beginning of Government Indemnification*** The earliest law to consider liability protection for national defense contracting was passed nearly 50 years ago. In Public Law 85-804, Congress authorized the president to contract for facilitation of the national defense. Executive Order 10789 (as amended) provided that the government could partially indemnify contractors for risks defined in the contract as "unusually hazardous or nuclear" [FAR 52.250-1(c)]. Shortly after September 11, 2001, Executive Order (EO) 13232 extended that contract authority to HHS.

Indemnity under PL 85-804 and EO 10789 (as amended) covers claims for death, personal injury, or loss of or damage to property if the contract contains language specifying that a particular risk is "unusually hazardous or nuclear." Contractors are not indemnified for claims within deductible amounts of insurance. Additionally, protection under PL 85-804 extends only to negligent acts or omissions; indemnification is not available for willful misconduct or bad faith. To be eligible for indemnification, the contractor must notify the United States of any claims against it, and the United States reserves a right to "control or assist" the settlement or defense. Therefore, although this indemnification grant was revolutionary at the time it became law, it only applies in limited circumstances: claims for negligence that arise from contractually defined unusually hazardous or nuclear activities.

***The Smallpox Act*** After September 11, 2001, with attention focused on contracting with the private sector to facilitate terrorism prevention, relevant liability protection laws were passed in an attempt to address particular concerns related to terrorism. The HSA in 2002 included a provision commonly referred to as the Smallpox Act, which covered manufacturers and distributors of medical countermeasures [67]. Under the Smallpox Act, the Secretary of DHS must declare that an actual or potential bioterrorist incident or public health emergency exists and designate certain countermeasures to be covered. If those conditions were satisfied, the United States would then retain liability for any claim arising out of the administration of those designated countermeasures by a qualified person.

***The SAFETY Act*** Also included in the 2002 HSA was the SAFETY Act. The SAFETY Act empowers the Secretary of DHS to designate certain products as "qualified anti-terrorism technologies" (QATTs) [66, at § 863(1)]. The act limits liability when those technologies are deployed in defense against, response to, or recovery from an act of terrorism by creating an exclusive federal cause of action and indemnifying sellers of the technologies from liability to third parties arising out of an act of terrorism.

Like PL 85-804, the SAFETY Act indemnifies sellers of QATTs only for liability amounts above a specified level of insurance coverage that is set forth in an individual contract. If the SAFETY Act protections for QATTs are applicable, plaintiffs may not seek punitive damages, recovery is limited to economic damages, and noneconomic damages are available only in proportion to the percentage of responsibility of the defendant, reduced by any other compensation received by the plaintiff. SAFETY Act protections do not apply to willful misconduct or fraudulent actions by the contractor [66, at § 863(b)].

In addition to potential designation of a technology as a QATT, the SAFETY Act provides further protection for technologies that are certified as eligible for the government contractor defense. Certified QATTs have the benefit of a rebuttable presumption that the government contractor defense, which shields contractors from liability for third-party tort claims, applies to third-party tort claims resulting from an act of terrorism. Only a

showing of fraud or willful misconduct will allow a plaintiff's claim to go forward [66, at § 863(d)].

***The PREP Act*** The Public Readiness and Emergency Preparedness (PREP) Act, part of the DoD authorization bill for 2006, provides liability protection to manufacturers, distributors, and program planners for pandemic and epidemic products and medical countermeasures [68]. The Secretary of HHS can designate a product to be covered by the act. To do so, the Secretary must find that a "disease or other health condition or other threat to health constitutes a public health emergency" or that there is a "credible risk" of such an emergency in the future [66, at § 319F-3(b)]. By its terms, the PREP Act appears only to cover pandemic disease scenarios and does not cover terrorism, but it is conceivable that a bioterrorism attack would constitute a pandemic or epidemic public health emergency and therefore fall under the purview of the PREP Act.

Once the Secretary of HHS has declared a medical countermeasure to be a pandemic countermeasure to an existing threat to public health, PREP Act liability protections apply. Liability protection in the form of immunity from suit exists for losses that were "caused by, arising out of, relating to, or resulting from" use of a medical countermeasure [66, at § 319F-3(a)] by the distributor, manufacturer, or program planner [66, at § 319F-3(c)]. The sole exception to this immunity is for federal causes of action regarding death or serious physical injury proximately caused by willful misconduct [66, at § 319F-3(d)]. In those cases, damages would be reduced by any collateral source benefits [66, at § 319F-3(e)(8)] and noneconomic damages could only be recovered according to the percentage of responsibility of the defendant [66, at § 319F-3(e)(7)].

The PREP Act also creates a fund to cover compensation for injuries that result directly from administration or use of a covered countermeasure under a declaration by the Secretary of HHS. While some critics were hoping for clarity as to which injuries would be covered, the PREP Act does not provide much guidance. It refers to authority in existing statutes that require the Secretary of HHS to compile tables of known side effects of vaccines and to provide a complete list of covered injuries [66, at § 319F-4(b)(4) & (5)]. According to the statute, when the Secretary makes a declaration under the PREP Act, a table of eligible side effects or injuries should also be issued.

There has only been one declaration under the PREP Act of a pandemic or epidemic threat to public health. In early 2007, the Secretary of HHS issued a declaration in the *Federal Register* that the avian flu virus posed a potential future pandemic threat if it were to evolve into human influenza [69]. The declaration recommended "manufacturing, testing, development and distribution . . . of the pandemic countermeasure influenza A (H5N1) vaccine," which targets avian flu. Therefore, although the PREP Act provides significant liability protection, the only people it currently covers are manufacturers, distributors, and program planners for one medical countermeasure: the avian flu vaccine.

## 4 REGULATORY RESTRICTIONS AFFECTING RESEARCH

This section describes key regulatory restrictions applicable to those who conduct research involving biodefense products. This discussion is intended only as a general introduction to this topic. Those who intend to engage in biodefense-related research must ensure that they are familiar with the many complex laws and regulations that apply in this field and take appropriate steps to comply.

### 4.1 Select Agent Regulations

In the wake of the Oklahoma City bombing of the Alfred E. Murrah Building in April 1995, Congress passed the Antiterrorism and Effective Death Penalty Act of 1996 in October 1996 (AEDPA). As part of the implementation of this act, the first list of regulated biological agents was created [70]. This became known as the "select agent" list.

After the terrorist events of September and October 2001, Congress passed the Uniting and Strengthening America by Providing Appropriate Tools Required to Intercept and Obstruct Terrorism Act of 2001 (USA PATRIOT Act or PATRIOT Act). This was followed in June 2002 by passage of the Public Health Security and Bioterrorism Preparedness and Response Act of 2002 (Bioterrorism Act), which expanded the Select Agent Program. Both the PATRIOT Act and the Bioterrorism Act contained provisions to tighten the regulation of the possession, use, and transfer of "select agents," biological agents, and toxins with the potential to pose a severe threat to public health and safety, animal and plant health, or animal and plant products [71].

The PATRIOT Act placed restrictions on persons who possess select agents and established criminal penalties for illegal possession of such agents [72]. Section 202(a) of the Bioterrorism Act required that all persons possessing biological agents or toxins deemed a threat to public health provide notice to the Secretary of HHS [73], while section 213(b) required all persons possessing biological agents or toxins deemed a threat to animal or plant health and to animal or plant products to notify the Secretary of the U.S. Department of Agriculture (USDA) [73, at § 213(b)].

**TABLE 3 Examples of HHS and USDA Select Agents**[a]

| HHS Select Agents | USDA Select Agents | Overlap Agents |
|---|---|---|
| Cercopithecine herpesvirus (Herpes B virus) | African horse sickness virus | *Bacilius anthracis* |
| Conotoxins | African swine fever virus | Botulinum neurotoxins |
| Crimean-Congo hemorrhagic fever virus | Avian influenza virus (highly pathogenic) | *Brucella* (*abortus*, *melitensis*, and *suis*) |
| Ebola viruses | Bovine spongiform encephalopathy (BSE) agent | Burkholderia |
| Marburg virus | Camel pox virus | *Clostridium perfringens* epsilon toxin |
| Monkeypox virus | Classical swine fever virus | *Coccidiodes immitis* |
| Reconstructed 1918 influenza virus | Foot-and-mouth disease virus | *Coxiella burnetii* |
| Ricin | Japanese encephalitis virus | Eastern Equine Encephalitis virus |
| *Rickettsia rickettsii* | Peste des petits ruminants virus | *Francisella tularensis* |
| Variola major virus (Smallpox) | Rinderpest virus | Rift Valley fever virus |
| *Yersinia pestis* (plague) | Swine vesicular disease virus | Staphylococcal enterotoxins |

[a]For the complete and up-to-date lists, refer to the HHS and USDA regulations, currently found at 42 CFR § 73.7(a); 9 CFR § 121.7(a).

HHS and USDA published final rules in March 2005 implementing the select agent provisions of the PATRIOT Act and the Bioterrorism Act [74]. The regulations establish the agencies' respective lists of select agents (Table 3) and provide that "an individual or entity shall not possess, use, or transfer any . . . select agent or toxin without a certificate of registration issued by the . . . Secretary [or Administrator]" [42 CFR § 73.7(a); 9 CFR § 121.7(a)]. The regulations also establish a process to document successful transfer of agents; audit, quality control, and accountability mechanisms; and agent disposal requirements.

To receive the requisite registration certificate, the HHS Secretary or Administrator of the USDA's Animal and Plant Health Inspection Service (APHIS) must approve, based on a security risk assessment by the Attorney General, the individual or entity, responsible official, and any individual who owns or controls the entity [42 CFR § 73.7(c)(1); 9 CFR § 121.7(c)(1)]. The issuance of a certificate of registration may be contingent upon inspection or submission of additional information, such as a security plan, biosafety plan, or incident response plan [42 CFR § 73.7(f); 9 CFR § 121.7(f)]. An individual who transfers select agents to a person the transferor knows or has reason to believe is not registered according to the provisions in 42 CFR § 73 is subject to criminal penalties [18 USC § 175b(b)]. Similarly, any person who knowingly possesses a select agent without the requisite registration shall be fined, or imprisoned, or both [18 USC § 175b(c)].

Some select agents or toxins are excluded from regulation. One such exception applies to toxins under the control of a principal investigator, treating physician or veterinarian, or commercial manufacturer or distributor, so long as the aggregate amounts do not exceed those provided in the regulations [42 CFR § 73.4(d)(3)]. An example of this is botulinum neurotoxins, for which an exemption is provided if the aggregate amount under the control of a principal investigator does not, at any time, exceed 0.5 mg [42 CFR § 73.4(d)(3)]. The exception is intended to "balance the regulatory oversight of agents and toxins that have the potential to pose a severe threat to public health and safety while maintaining availability of these agents and toxins for research and educational activities" (70 *Fed Reg* 13297). Other exemptions apply to select agents used in products approved, licensed, or registered under federal laws including the FFDCA, section 351 of the Public Health Service Act (pertaining to biological products), and the Federal Insecticide, Fungicide, and Rodenticide Act [42 CFR § 73.5(c)].

The serious consequences of violating the select agent rules was highlighted by the case of Dr. Thomas Butler, a researcher at Texas Tech University. Dr. Butler brought plague samples back from Tanzania for research purposes, did not declare them at Customs, and drove from Lubbock, Texas, to a CDC laboratory in Colorado to have the samples tested, all without the necessary government permits [75]. Dr. Butler later sent samples back to Tanzania and flew with the samples from Lubbock to Washington D.C., again without the necessary paperwork. After Dr. Butler reported to his local health department that 30 plague vials were missing, the FBI arrested Dr. Butler [75]. Dr. Butler was eventually convicted on 47 of 69 criminal charges, resulting in a 2-year prison term [76]. Included in his conviction were 3 counts relating to the transportation of human plague bacteria, *Yersinia pestis*, an HHS select agent.

### 4.2 Biosafety Laboratories

The CDC and NIH prepared the Biosafety in Microbiological and Biomedical Laboratories (BMBL) as a guidance document for working with particular select agents. The BMBL states that biosafety procedures must be incorporated into the laboratory's standard operating procedures or biosafety manual;

personnel must be advised of special hazards and are required to read and follow instructions on practices and procedures; and personnel must receive training on the potential hazards associated with the work involved and the necessary precautions to prevent exposure [77].

The anthrax attacks in 2001 highlighted the shortage of high-containment lab capacity available to conduct research leading to the development of medical countermeasures [78]. To address this concern, the Bush Administration and Congress responded by providing increased funding for biodefense research and for additional Biosafety Level 3 (BSL-3) and Biosafety Level 4 (BSL-4) labs in the private sector, especially in university settings [78].

As a result, since September 11, 2001, there has been a "major proliferation" of high-containment BSL-3 and BSL-4 laboratories in the United States across all sectors—federal, academic, state, and private [78]. However, concerns have been raised about the oversight of these labs. No single federal agency is accountable for tracking the number of all BSL-3 and BSL-4 labs within the United States, and no agency knows how many such labs there are in the United States or the locations of the labs [78]. Information on expansion is available about high-containment labs that are registered with the CDC–USDA's Select Agent Program and/or are federally funded, but much less is known about the expansion of labs outside the Select Agent Program and the nonfederally funded labs, including location, activities, and ownership [78].

Before 1990, all BSL-4 labs were federal labs. Today, while expansion is taking place within the federal sector as well, there are also BSL-4 labs at universities, as part of state response, and in the private sector [78]. The expansion of BSL-3 labs is also taking place within all sectors. However, the only definitive data available are on labs registered with the CDC–USDA Select Agent Program. Within that program, two-thirds of registered BSL-3 labs are outside the federal sector [78].

This growth in government and privately owned high-containment laboratories has led to concerns about the potential for unintentional releases of dangerous agents. Recent incidents in the United States and England indicate the hazards associated with these labs. One NIAID-funded facility, at Texas A&M University—registered with CDC's Select Agent Program and approved for work on several select agents—was found to have allowed unauthorized access to high-security laboratories and to have misplaced vials of infectious agents [79]. A 21-page report issued by the CDC and released in late August 2007 followed months of scrutiny over the university's failure to report laboratory workers being exposed to dangerous biological agents [79]. As a result of its failures, the lab was banned from select agent research and required to undertake corrective actions [79].

Also in the summer of 2007, contamination of foot-and-mouth disease was discovered at several local farms near Pirbright, England, the site of several high-containment labs that work with live food-and-mouth disease virus, one of the most highly infectious livestock diseases [78]. An investigation of the site found evidence of long-term damage and leakage of the drainage system servicing the site. Although the definitive cause of the release has not been determined, it is suspected that contaminated wastewater from Pirbright's labs leaked into the surrounding soil from the deteriorated drainage pipes and that live virus was then carried offsite by vehicles splashed with contaminated mud [78]. The investigation revealed that monitoring and testing for the preventative maintenance of pipework for the drainage system was not a regular practice on site [78]. This incident shows that beyond initial design and construction, ongoing maintenance plays a critical role in ensuring that high-containment labs operate safely and securely over time, because even the smallest of defects can affect safety.

Perhaps in response to the Texas A&M violations and the incident in England, the House Committee on Energy and Commerce held a hearing in October 2007 on potential risks from BSL-3 and BSL-4 laboratories in the United States [80]. The public and congressional attention on this issue is likely to refocus U.S. regulators' attempts to ensure compliance with applicable biosafety standards and may make it more difficult in the future to obtain registration of a new biosafety laboratory.

### 4.3 Export Controls

U.S. law imposes strict controls on the export of sensitive biological agents, products designed to produce and defend against such agents, as well as related technology. U.S. export controls apply not only to transfers and international collaborations across borders, but also to transfers to "foreign nationals" within the United States.

Most open research work on university campuses in the United States falls under fundamental research exclusions and does not trigger licensing requirements for access by non-U.S. scientists in the United States. The research must be eligible for publication without restriction by the university or the project sponsors, and eligible for open access by all. These exclusions generally cover work on campus and, frequently, do not extend to international collaborations.

Any research and development work not eligible for the fundamental research protections falls under the International Traffic in Arms Regulations (ITAR)

or the Export Administration Regulations (EAR). Category XIV of the ITAR controls toxicological agents, including chemical agents, biological agents, and associated equipment (22 CFR § 121.1). The biological agents controlled are narrow and specific and only cover those agents developed or modified to cause harm.* Any medical countermeasures specifically designed or modified for the sole purpose of protecting against the biological agents controlled in ITAR Category XIV would require a State Department license for export from the United States or access to related technical data in the United States by anyone other than a U.S. citizen or permanent resident. Similarly, any equipment specifically designed or modified for military operations and compatibility with military equipment would fall under these stringent controls.

Most research and development work in the bioterrorism area falls under the jurisdiction of the Commerce Department's Export Administration Regulations. The most sensitive human and zoonotic pathogens and toxins, as well as certain sensitive animal pathogens and their genetic elements, require licenses for export from the United States to every destination. Similarly, only U.S. citizens and permanent residents may access in the United States without a license the technology for the development, production, and disposal of the most sensitive agents [81]. Equipment designed to detect, monitor, and defend against biological agents may trigger a license requirement not only for export to certain destinations but also for access to the technology for the development and production, and in some cases use, of the related technology [82].

## 5 CONCLUSION

This chapter reviews the significant efforts of Congress and the executive branch of the U.S. government to create the right incentives for the private sector to develop medical countermeasures. These measures, together with important changes in public health surveillance and delivery, are designed to enhance the ability of the United States to reduce the risk of, and improve its ability to recover from, a bioterrorist attack. While there have been impressive gains made in this area, most observers believe that the intensity and pace of change needs to accelerate to counter the growing threat of bioterrorism. These same programs and efforts also help in the fight against important naturally occurring infectious diseases and pandemics. Researchers or entities considering development programs in these therapeutic areas should stay abreast of future measures that may be of benefit to their development programs.

*Category XIV(b) controls "Biological agents and biologically derived substances specifically developed, configured, adapted or modified for the purpose of increasing their capability to produce casualties in humans or livestock, degrade equipment or damage crops."

## ACKNOWLEDGMENT

The authors would like to thank their colleagues John Barker, Jennifer Newberger, and Lindsay Rodman for their assistance in preparing this chapter.

## 1 INTRODUCTION

### 1.1 Antibodies Constitute Natural Host Defense

Living organisms are continually challenged by pathogenic infections that, if allowed to persist, may result in severe disease and death. The role of the immune system is to identify, and bind to, the molecular determinants (called *epitopes*) of such pathogens, leading to their elimination from the host [1]. The challenge faced by the immune system is to identify a relatively small number of foreign substances, or antigens, against the much broader background of self and otherwise harmless or even beneficial agents (including ingested foods and pharmaceuticals). Failure to obtain sufficient discrimination between host and foreign tissue results in a wide spectrum of autoimmune pathologies, while cancer may arise, in part, due to the inability of the body to distinguish malignant from healthy cells.

The humoral adaptive immune response is mediated by soluble immunoglobulin molecules (antibodies) secreted by B cells that bind to foreign antigens and, through interactions with other components of the immune system, play a pivotal role in eliminating them from the organism [1]. The surfaces of pathogens, such as bacteria and viruses, have high molecular complexity with multiple potential (overlapping) epitopes. Each B cell secretes an antibody with a single specificity (monoclonal). A polyclonal response requires the participation of many B cells to provide effective coverage of the pathogen surface. The affinity of each specific antibody may differ, even against the same epitope. Through a process of clonal selection, the highest affinity antibodies are selected and become dominant in the serum.

### 1.2 Therapeutic Applications of Antibodies

The immune system can be modulated by the therapeutic application of antibodies with reactivity to host cell proteins. Monoclonal antibodies to human molecules can be obtained by immunization of laboratory species (such as mice) or by in vitro selection from synthetic libraries of antibody sequences displayed on the surfaces of microbes, such as filamentous bacteriophage [2, 3]. The origin of the antibody diversity is critical; antibodies from foreign organisms (and even purely human antibodies) can function as antigens when injected, prompting a rapid clearance and/or full immune response. Genetic engineering of the antibody sequence can be used to reduce the immunogenicity of antibodies. Native antibodies function both by blocking critical protein–protein interactions necessary for pathogen attachment and by recruiting effector cells to mediate destruction and clearance of the invading organism. Therapeutic antibodies may also be used to trigger a

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

native immune response against a disease-causing agent, either foreign or native. For some applications, such as diagnostic reagents or as targeting agents for drug delivery vehicles, the effector domains are unnecessary (or potentially deleterious) and are removed from the protein sequence, either pre- or posttranslation.

Antibodies that bind to foreign antigens are (generally) not highly cross-reactive with host proteins (although there are exceptions in autoimmune pathologies). However, application of therapeutic antibodies directed against host cell adhesion proteins faces the unavoidable dilemma that the same proteins that contribute to the disease pathology have normal physiological functions [4]. For example, nonselective blockade of immune adhesion molecules, such as integrins, can contribute to broad-based immune deficiency, necessitating a trade-off between the need for disease suppression and the potential for (severe) side effects.

### 1.3 Cell Adhesion Molecules as Therapeutic Targets

Cell adhesion is a critical component of all disease mechanisms; for example, foreign organisms must establish a foothold in the host to survive and propagate. Tumor cells use endogenous cell surface molecules to spread throughout the organism, and autoimmune disorders require cell adhesion molecules for the trafficking and accumulation of immune cells at inflammatory sites [5–7]. Microbial adhesins are inviting targets to the host humoral immune system given the functional requirement that they be displayed on the pathogen surface in an accessible conformation [8]. Autoimmune disorders as well as cancers present more difficult targets for the immune system because the host cell adhesion and migration machinery is intimately involved in disease progression but is intrinsically recognized as self, putting it beyond the reach of endogenous immunoremediation.

### 1.4 Integrins Undergo Substantial Activation-Dependent Conformational Changes

Of the major classes of adhesion receptors, including the immunoglobrin domain superfamily (IgSF), the cadherins, and other transmembrane adhesion receptors (e.g., claudins and occludins), integrins are unique in achieving rapid and reversible (second time scale) upregulation from a basal, inactive state to a maximally adhesive state, upon cell stimulation [5–7]. Other adhesion receptors require in-membrane diffusion (both active and passive) and/or regulation of cell surface expression levels to modulate the magnitude of adhesion. The dramatic increase in affinity is obtained by a series of conformational changes that increase the affinity of the integrin for ligand and enhance the accessibility of the ligand-binding site [9, 10] (Figs. 1 and 2).

A subset of anti-integrin monoclonal antibodies (mAbs) selectively recognizes the active (adhesive) conformation; some of these antibodies also simultaneously block integrin–ligand interactions [11]. In vivo, these antibodies are unlikely to bind to appropriately functional integrin since in these receptors adhesion is rapidly up- and then downregulated. By comparison, pathological adhesion is characterized by long-lived and sustained activation [12]. We have suggested, and subsequently demonstrated, that it is possible to selectively target persistently activated integrin in a physiological background [13]. In this chapter, we describe how such antibodies are derived, their mechanism of action, and their potential therapeutic application.

## 2 INTEGRIN STRUCTURE OVERVIEW

### 2.1 Integrins Are α/β Heterodimeric and Multidomain Cell Surface Molecules

Integrins are noncovalently associated heterodimers that consist of 1 (of 18) α and 1 (of 8) β subunits with 24 known combinations (excluding splice variants) [14]. Both α and β are single-pass type-I transmembrane glycoproteins with complex, multidomain extracellular architecture and a generally (excluding $\beta_4$) short cytoplasmic sequence (Fig. 1). High-resolution structural techniques [crystallography and nuclear magnetic resonance (NMR)], electron microscopy (EM), and biochemical/bioinformatics analysis (i.e., disulfide mapping and multiple sequence alignment) have been used to assemble a structural model of integrin domains and their role during the transition from the inactive to active state of the integrins [15, 16].

The β-propeller domain and the I domain in the α subunit and the I-like domain in the β subunit form a globular "integrin head" that contains the ligand-binding function (Fig. 1). The integin headpiece, which includes the integin head, the thigh domain in the α subunit, and plexins, semaphornins, and integrins (PSI) and hybrid domains in the β subunit, is connected via the integrin legpiece to the plasma membrane (Fig. 1).

### 2.2 Integrin Extracellular Domains in the α Subunit

Integrin α subunits are approximately 1000 amino acids in length, organized in 4 or 5 extracellular domains (Fig. 1).

***β-Propeller Domain*** The N-terminal domain of the α subunit is a β propeller; each blade of the propeller is a

**Figure 1** Model for global conformational changes of the extracellular portion of $\alpha_L\beta_2$ integrin: (A) bent conformation (low affinity) and (B) extended conformation with open headpiece and open high-affinity I domain. The C-terminal I domain α helix is represented by a cylinder, and its downward shift upon activation is shown by an arrow. Integrin α and β subunits and integrin domains are labeled by black, location of epitopes of activation-dependent mAbs (i.e., AL-57, m24, KIM127, and NKI-L16) are shown by circles and labeled. (This figure is modified from [86].)

4-stranded antiparallel β sheet. In 9 of 18 α subunits, a domain of about 200 amino acids is inserted in a loop between blades 2 and 3 (the *I domain*). When present, the I domain forms all or part of the ligand-binding interface [17, 18].

***I Domain, A Major Ligand-Binding Domain*** The I-domain structure is a variant of the Rossmann dinucleotide binding fold; seven α helices wrap five parallel and one antiparallel β strands; the helices and strands generally alternate in the sequence topology (Figs. 1 and 2). Five amino acid side chains form a divalent cation-binding site (the metal ion dependent adhesion site, MIDAS) on the top face of the I domain. A ring of hydrophobic residues (the hydrophobic cup) surrounds the MIDAS. The I domain is joined to the β propeller on the opposite, bottom face where the N and C termini are in close proximity [10].

The I domain can assume two distinct conformations (termed *closed* and *open*) that differ in the coordination structure of the MIDAS and the relative position of secondary structural elements (Fig. 2) [10]. Compared to the closed conformation, the C-terminal helix (α7) in the open conformation is shifted downward by two turns. Also, a water molecule replaces an aspartic acid in the primary coordination sphere of a Mg(II) at the MIDAS. The loss of the direct interaction with the aspartic increases the electrophilicity of the metal. An acidic amino acid residue from a ligand or a neighboring molecule in the crystal lattice (in one structure of the αM I domain) displaces the bound water, compensating for the loss of the directly coordinating negatively charged aspartic acid. The interaction of a ligand acidic amino acid residue with the MIDAS in the open conformation is a canonical feature of integrin–ligand interactions [10].

The wild-type I domain from $\alpha_L\beta_2$ does not crystallize in the open conformation with a ligand-mimetic contact [19], consistent with the failure of the isolated I domain to constitutively bind the ligand ICAM-1 ($K_D$ I domain: ICAM-1 ~1 m*M*) [20]. Using the open structure of the $\alpha_M$ I domain as a template, an engineered disulfide bond was introduced into the αL domain sequence to stabilize the α7 helix in the open conformation [20]. Surface plasmon resonance (SPR, commonly referred to as BIACORE) was used to obtain the binding kinetics of the wild-type and locked-open I domains for immobilized ligand ICAM-1. The affinity of the $\alpha_L$ I domain for

**Figure 2** Activation-dependent conformational changes of the $a_M$ I domain. The regions with significant conformational changes are dark colored, while those with similar backbones are light colored. $Mg^{2+}$ ions (spheres) and side chains of metal-coordinating residues (ball-and-stick representations) are shown. A downward shift of the C-terminal helix (dashed arrow) and the conversion of the MIDAS to the high-affinity configuration (boxed). (This figure is modified from [87].)

the ligand increased $10^4$-fold over the wild-type sequence when the C-terminal helix is locked in the downward position by the engineered disulfide bond [20]. A crystal structure of the "high affinity" locked-open I domain reveals that movement of the C-terminal helix triggers conformational changes that were observed in the open conformation of the $\alpha_M$, including a reorganization of the coordination sphere surrounding the MIDAS and repositioning of surrounding loops to increase complementarity with the bound ligand. In the co-crystal with domains 1–2 of ICAM-1, the side-chain carboxylate E-34 of domain 1-ICAM-1 coordinates the MIDAS metal. Additional polar and electrostatic interactions surround the hydrophobic cup and make complimentary contacts on the surface of ICAM-1 [21].

***Thigh, and Calf Domains*** C terminal to the β propeller is the *thigh*, a β-sandwich domain that is topologically similar to an immunogloblin fold (Fig. 1) [15]. The *genu*, a short disulfide bonded loop that includes a calcium coordinating site is situated between the thigh and *calf-1* domain. Both calf-1 and *calf-2* domains are also β-sandwich domains. In most integrins that lack an I domain in the β propeller ($\alpha_3$, $\alpha_5$, $\alpha_6$, $\alpha_8$, $\alpha_V$, and $\alpha_{IIb}$ but not $\alpha_4$ or $\alpha_9$) there is a furin protease cleavage site in calf-2 that separates the α subunit into heavy and light chains.

### 2.3 Integrin Extracellular Domains in the β Subunit

The β subunit contains about 640 amino acids organized into 8 extracellular domains (Fig. 1).

***PSI and Hybrid Domains*** The N terminus of the β subunit is a 54-residue cysteine-rich sequence with significant homology to plexins and semaphorins and has been accordingly named the PSI domain [15]. The sequence folds into a 2-stranded antiparallel β sheet flanked by a pair of short α helices that are linked to the sheet by disulfide bonds; a short N-terminal segment may also form an α-helix. Significantly, the fourth disulfide bond of the PSI is to a stretch of amino acids that is C terminal to the adjacent hybrid domain; thus, the hybrid domain is actually inserted within the PSI sequence. The *hybrid domain* is also an immunogloblin domain.

***I-Like Domains and a Ligand Binding and/or Key Regulatory Domain*** Inserted into the B–C loop of the hybrid domain is the *β I-like (βA)* domain, which is structurally homologous to the I domain found in half of all α subunits. In addition to the MIDAS there are two additional metal coordination sites that share coordinated residues with the MIDAS and regulate the affinity of the βA domain for ligand, the adjacent to MIDAS (ADMIDAS) and the ligand-induced metal binding site (LIMBS) [22, 23].

The structure of αvβ3 bound to the cyclic pentapeptide {Arg-Gly-Asp-{D-Phe}-*N-methyl*-Val} P5 was obtained in the presence of the activating cation Mn(II), revealing many of the crucial features of integrin–ligand interactions [22, 23]. P5 binds in a crevice between the β propeller and the βA domain, burying 355Å (45% of the peptide surface area). The arginine and aspartic acid side chains of the peptide are oppositely disposed. The arginine is pointed toward the β propeller, inserting into a narrow groove formed from the D3–A3 and D4–A4 loops, held in place by a bidentate salt bridge to a pair of aspartic acids within the groove. The ligand Asp points toward the βA domain where one of the carboxylate oxygens completes the coordination sphere of the Mn(II)-bound MIDAS. While the ligand arginine is partially solvent exposed, the ligand aspartic acid is completely buried in the complex, with the second oxygen forming a network of polar interactions with backbone amides and the aliphatic side chain making hydrophobic contacts with protein side chains. The glycine sits at the

interface between α and β subunits, making hydrophobic contacts with residues in the α chain. Notably, the bond conformation of the RGD segment is similar to free conformation of the natural ligand echistatin, validating the physiological relevance of the structural analysis of the small-molecule ligand mimetic. The two additional residues in the peptide point away from the α/β interface.

The βA domain undergoes structural changes homologous to the α I domain upon binding ligand including a repositioning of the β6–α7 loop and downward piston-like motion of the C-terminal α7 helix. As a result of the downward motion, the hybrid and PSI domains are swung away from the α/β interface by ~62°. The motion of the hybrid domain is presumably the mechanism by which conformational changes in the ligand-binding site are propagated to C-terminal domains [23].

***Integrin–Epidermal Growth Factor (EGF) (I-EGF Domains)*** C terminal to the βA domain, four cysteine-rich segments fold into *EGF domains 1–4* (Fig. 1). The canonical EGF domain is 30–40 amino acids, with two β sheets, the major sheet at the N terminus and the minor sheet at the C terminus, and three disulfide bonds, two of which (at the N terminus) are interleaved in the sequence [24]. The integrin EGF repeats differ in having a fourth intradomain disulfide bond (all I-EGF-1 and I-EGF-3 of $\beta_4$ and $\beta_8$ also have a distinct arrangement of disulfide bonds from other I-EGF domains) [25].

***The β Tail Domain*** The *beta terminal domain (βTD)* is the most C-terminal extracellular domain of the β subunit, just prior to the transmembrane domain. The βTD is a novel fold, an N-terminal α helix facing a mixed parallel and antiparallel four-stranded β sheet.

### 2.4 Transmembrane Domains of α- and β Subunits

The *integrin transmembrane domains* are the critical point in transmitting extracellular ligand binding across the membrane into the cytoplasm. Solution NMR studies of the isolated $\beta_3$ transmembrane domains in detergent micelles suggest a structure that is largely helical [26]. A specific interface between $\alpha_{IIb}$ and $\beta_3$ in intact cell membranes was identified using disulfide cross-linking [27]. Sequence homology with other integrin transmembrane domains suggests that the interface is a conserved feature of all integrins in the resting state.

### 2.5 Cytoplasmic Domains of α and β Subunits

The *cytoplasmic tail domains* ("tails") are generally short; for example, the $\beta_3$ tail is 47 amino acids (aa) in length; the 2 associated α subunits ($\alpha_{IIb}$ and $\alpha_V$) are 20 aa and 32 aa, respectively. The cytoplasmic tail complex of $\alpha_{IIb}\beta_3$ has been studied by NMR spectroscopy and remains the only integrin tail structure to be determined at atomic resolution [28]. The $\alpha_{IIb}$ tail forms a short N-terminal α helix followed by a turn and a C-terminal loop that folds back onto the positive charged N-terminal helix. The structure of the $\alpha_{IIb}$ tail is similar in the absence and presence of $\beta_3$ tail. The $\beta_3$ tail also forms an N-terminal α helix; the remainder of the tail has no persistent structure, although the C-terminal N-P-L-Y sequence transiently populates a turn. The interface between the two tails is composed of both hydrophobic and electrostatic interactions contributed by the membrane-proximal helices. Most α subunits have a conserved G-F-F-K-R sequence in the juxta-membrane region (although in α10 this is replaced by a G-A-H-K-K sequence). $\alpha_{IIb}$-R-995 forms a conserved salt bridge with $\beta_3$-D-723 that plays a crucial role in restraining integrins in the inactive state [29]. Multiple serine, threonine, tyrosine (and possibly histidine) residues on both α and β tails are available for phosphorylation, which both regulates the interaction between the tails and the avidity of the tails for other cytoplasmic proteins [30].

### 2.6 Integrin Structure and Activation Mechanism

The integrin heterodimer is generally divided into two distinct regions. The head (or headpiece) is formed from the α-subunit propeller and I domain and the β-subunit βA and PSI domains. The legs (sometimes known as the tailpiece, not to be confused with the cytoplasmic tails) is formed from, the calf-1, calf-2, and thigh domains of the α subunit and the EGF and β-tail domains of the β subunit.

In the crystal structure of $\alpha_V\beta_3$, the integrin is folded into a V-shaped conformation with a 135° angle between the head and tail domains [22]. The bend occurs between the thigh and calf-1 domains in the α chain and between the I-EGF-1 and I-EGF-2 domains in the β subunit (specifically, at the genu). As a result, the ligand-binding head is pointed toward the cell surface where it is not accessible to ligands in the extracellular matrix or on the opposing cell surface. The bend also results in the formation of extensive buried and partially buried inter- and intrasubunit interfaces and restricts the flexibility of interdomain motions, such as the ability of the hybrid domain to attain the swung-out conformation [31].

The *switchblade model of integrin activation* proposes that integrins exist in two global conformations: bent (as observed in the crystal structure of $\alpha_V\beta_3$) and extended (Fig. 1) [15, 25]. The bent conformation is stabilized by a number of intra and intersubunit interfaces. Prior to activation, the two conformations are in exchange, with the equilibrium shifted heavily toward the bent

conformation. Dissociation of the cytoplasmic domains occurs upon binding of cytoplasmic proteins (such as talin) to the tails, triggering separation of the transmembrane domains and the interface between the legs. Separation of the α/β legs further destabilizes the interface between the legs and the headpiece domains, permitting the receptor to attain the fully extended conformation. In the extended conformation, the head domains are well disposed to bind ligands. Once the integrin is extended and the legs fully separate, the hybrid domain can swing out, maximally activating the integrin for ligand binding. The switchblade model accounts for the binding of many conformationally selective mAbs since the binding epitopes for many of these mAbs are buried (or partially buried) in the bent conformation but become exposed in the extended and fully activated (extended with hybrid domain out) conformations [25, 31].

**Figure 3** Class I (A) and class II (B) conformational selective antibodies. (A) Antigenic epitopes are shielded from binding in one conformation but become (more) accessible after activation. (B) Antigenic epitopes that are formed as a result of conformational change(s).

## 3 CONFORMATION-SELECTIVE ANTI-INTEGRIN MABS

The transition from the bent to extended (and then fully activated) conformation integrins requires disruption of protein–protein interfaces between domains (i.e., separation of the α and β legs) and allosteric motions within domains (i.e., conversion of the closed-to-open conformation of the I domain). In this section, we review select members of two classes of mAbs defined by epitopes that are gained (or lost) via each transition. We specifically emphasize properties of each antibody pertinent to evaluating their potential as therapeutic agents.

### 3.1 Class I Conformation-Selective Integrin Antibodies

***Class I*** The first class of mAbs binds to pre-existing epitopes that are shielded in one conformation but become (more) accessible in a second conformation (Fig. 3). mAbs in the integrin legs that become exposed upon α/β dissociation and receptor extension are of this type. Most such antibodies are in the cysteine-rich region of the β subunit, although the binding of anti-$\alpha_L$ genu mAb NKI-L16 and the anti-α5 calf-1/calf-2 mAb SNAKA51 are enhanced in activating conditions. The swing-out motion of the hybrid domain also differentially exposes epitopes on the protein surface.

***Monocromal Antibodies (mAbs) Binding to the Integrin Legpiece*** KIM127, NKLI-16, and SNAKA51 are three activation-sensitive mAbs that bind to epitopes in the integrin legs. KIM127 reacts preferentially with free (unpaired) integrin $\beta_2$ subunits and can promote binding by $\beta_2$ integrins to surface-immobilized ligand. The binding of KIM127 is temperature sensitive with considerably enhanced binding at 37° versus 4° [32, 33]. The binding of KIM127 to $\alpha_L\beta_2$ with activating mutations (i.e., mutation or truncation of the conserved G-F-F-K-R sequence in the cytoplasmic tail) is significantly upregulated. Addition of the activating reagents phorbol myristyl acetate (PMA) or Mn(II) also leads to increased KIM127 exposure. This illustrates a critical property of many activation-dependent antibodies. Due to the equilibration between bent and extended conformations, an activation-sensitive epitope will be transiently exposed; consequently, most activation-dependent mAbs have some potential to activate integrins.

The modest activation potential of KIM127 is explained by the position of the binding epitope. The epitope for KIM127 is located in a long loop at the C terminus of the I-EGF2 domain in the β stalk and contains the residues G-504, L-506, and Y-508 [25, 34]. Structurally adjacent to this loop are residues that restrain activation by $\beta_2$ integrins by hydrophobic packing interactions with the α subunit. I-EGF2 and I-EGF-3 are wedged into a bend formed at the genu with the KIM127 epitope located between the α-subunit thigh domain and the calf-1 domain. The tight packing of the interface effectively blocks binding of KIM127 prior to separation of the integrin legs. The epitope for the KIM185, an antibody with greater activating poten-

tial, includes residues in the I-EGF4 domain that are partially accessible to solvent in the bent conformation. The greater exposure of the KIM185 interface permits rapid binding of the mAb during the transient exposure in the equilibration between bent and extended conformations. Once bound, the mAb serves to block reclosure of the interface, which favors conversion to the extended conformation.

Most activation-dependent antibodies recognize epitopes on the β subunit. However, the mAb NKI-L16 [35, 36] and SNAKA51 [37] bind (preferentially) to the extended conformation of $\alpha_L$ and $\alpha_5$, respectively. In the basal, inactive state NKI-L16 binding to the $\alpha_L$ subunit is absolutely dependent on Ca(II) in a dose-dependent manner at concentrations between 0.1 and 10 m*M* Ca(II). The binding of NKI-L16 is enhanced upon addition of drug XVA143, which induces the extended conformation of αL. Residues on the inner face of the thigh domain, buried in the closed conformation by the calf-1 domain in the α subunit and the I-EGF2 and 3 in the β subunit, are required for binding of NKIL-16. Two absolutely critical residues, A-602 and W-738, are proximate in the three-dimensional structure of the thigh domain, close to the genu. Residues forming the Ca(II) coordination site in the genu and calf-1 domains are also required for binding. However, there are no human–murine substitutions within the highly conserved genu, and it is not clear if the Ca(II) is explicitly part of the binding site or merely stabilizes the conformation recognized by the mAb.

The binding of SNAKA51 requires both the calf-1 and calf-2 domains. SNAKA51 stimulates adhesion of $\alpha_5\beta_1$ to fibronectin fragments in a dose-dependent manner. Conversely, SNAKA51 reports on integrin activation in the presence of increasing concentrations of fibronectin ligand. Notably, truncation of the $\beta_1$ subunit tail does not affect mAb binding; however, the ability to activate $\alpha_5\beta_1$ by SNAKA51 is lost when the integrin β1 tail is truncated. This suggests that SNAKA51 activates by binding to the transiently opened leg conformation and acts as a wedge to keep the α and β legs separate, promoting integrin extension.

***mAbs Binding to the Hybrid and I-Like Domains*** The binding of mAbs to epitopes that lie directly within, or adjacent to, the hybrid domain can modulate, or be modulated by, integrin activation. The epitope of SG/19 a function blocking anti-β1 mAb, for example, includes T-82 in the hybrid domain (Fig. 1), on the fully exposed side of the domain opposite the α/β interface [38]. The epitope of SG/19 is close, in a three-dimensional model of $\beta_1$, to the binding site of SG/7 and mAb13, both of which also function as blocking anti-$\beta_1$ mAbs. Binding of this group of mAbs is significantly attenuated in a β1 mutant with the hybrid domain locked in the active, out conformation. Negative stain EM images of Fab SG/19 bound to a recombinant integrin headpiece fragment conform that Fab binds to the boundary between the βA and hybrid domains on the opposite side of the α/β subunit interface, including segments of both the hybrid and βA domains. The binding interface is incompatible, due to steric interactions, with the swung-out conformation of the hybrid domain, confirming the conclusion that this class of antibodies works by inhibiting this pivotal motion.

A number of $\beta_2$-function blocking mAbs (i.e., GFR1, YFC51.1, YFC118.1, CLB LFA1/1, and CLB 54) map to epitopes that are buried or partially buried in the residues K-133, H-332, and Y-339, which are in a similar position as the SG/19 class of anti-β1 mAbs, suggesting that they might inhibit $\beta_2$ integrin function by a similar mechanism [39].

The epitopes for a reciprocal group of mAbs that includes 15/7 and HUTS-4 involve a triplet of spatially proximate residues (S-370 and E-371 on the C–D loop, and K-417 on the adjacent E–F loop) that are within the inner face of the hybrid domain, at a small interface with the α-subunit β propeller [40]. In the inactive conformation, K-417 is accessible (to a 20-Å sphere) but both S-370 and E-371 are buried. Upon activation [by divalent cations such as Mn (II) or activating mutations] the antibody epitopes become exposed. A similar activation reporter mAb, MEM148, is located on the inner face of the $\beta_2$-subunit hybrid domain [41]. In the inactive conformation, the most critical residue in the epitope, P-374, is located at a three-way interface between α and β subunits as well as the α/β headpiece/tailpiece interface (residues H370-Q373 also form part of the epitope). The presence of hybrid domain epitopes that both support and suppress integrin activation are a function of the role of the hybrid domain as a nexus of conformational change between the ligand binding and leg domains.

### 3.2 Class II Conformation-Selective Integrin Antibodies

***Class II*** The second class of mAbs is to antigens with epitopes formed as a result of conformational change(s) bring spatially distant amino acid side chains within the 100-Å footprint of the 6 mAb complementary determining region (CDR) loops (Fig. 3). mAbs to integrin I and βA domains (Figs. 1 and 2) are typically class II antibodies with epitopes that are formed (or lost) due to the intradomain allosteric transition. The extent of this conformational preference is directly related to the extent to which the binding epitope of the antibody binding epitope lies within more plastic segments of the I domain. Generally, since the closed conformation is the

default state of the I domain, most antibodies have weak to modest selectivity that disfavors binding to the open conformation (by about 2- to 10-fold). For example, the mAb HI111 binds the $\alpha_L$ I domain with a $K_D$ about 5-fold lower for the closed than the open conformation (as determined by SPR analysis of soluble αL I domain binding to randomly immobilized mAb) [42]. The epitope of HI111 includes K-268 at the top of the α5 helix, a residue located near the MIDAS, which undergoes substantial conformational change in the closed-to-open conformation.

***mAbs Binding to the $\alpha_M$ I Domain*** A number of conformationally selective mAbs that bind to the $\alpha_M$ I domain have been obtained using the immunization–hybridoma technique. Conformationally selective mAbs can bind to—and inhibit the activity of—the I domain either by direct competition with ligand or by inhibiting requisite conformational changes, stabilizing the closed conformation. Two mAbs that illustrate this property are mAb-107 and 44a.

*mAb-107* The mAb-107 is an antibody that was identified from a hybridoma screen for mAbs with divalent cation dependence for binding to the isolated $\alpha_M$ I domain [43]. In addition to blocking binding of $\alpha_M\beta_2$ (and the isolated I domain) to soluble and immobilized ligand, mAb-107 inhibits spreading and opsonization by neutrophils, both $\alpha_M\beta_2$-dependent processes. The $K_D$ of $\alpha_M$ I domain is about sevenfold higher for $\alpha_M$ in the open conformation than for the wild-type I domain. Of the residues found in the binding epitope (G-143, E-178, E-179, R-208, and F-246) only F-246 (equivalent to T-243 in $\alpha_L$) shifts position in the high-affinity conformation, and it is presumably through this residue that the conformational selectivity of the mAb is obtained.

*44a* The antibody 44a has even higher selectivity for the closed ($K_D$ 4.4 n*M*) versus open conformation (860 n*M*) of $\alpha_M$ [44]. The epitope for the mAb is distinct from the MIDAS binding site, mapping to residues M-153–T-159 (α1 helix), E-162–L-170 (β2–β3), and Q-309–E314 (α7). The C-terminal α7 helix undergoes an obligate conformational change between closed and open conformation, as described in the structural overview, and the ability to block ligand blocking by 44a likely involves allosteric inhibition of this transition.

*CBRM1/5* Although most mAbs bind with (at least modest) selectivity to the closed, default conformation, a subset preferentially recognizes the open I domain conformation. CBRM1/5 binds selectively to the open (active) conformation of the $\alpha_M$ I domain and blocks ligand binding [45]. The mAb was isolated from mice immunized with intact, purified $\alpha_M\beta_2$. CBRM1/5 was identified using a screen for mAbs that bound to PMA-activated, but not resting, neutrophils. The total number of epitopes on an N-formyl-methionine-leucine-phenylalanine–stimulated (fMLP-stimulated) neutrophil is about 10% of that obtained from a non-conformationally selective mAb (30% of neutrophils activated by PMA), suggesting that only a fraction of the receptors on the surface are in the active conformation after stimulation. Although CBRM1/5 binds to only a small fraction of αM on the cell surface, saturating concentrations of mAb completely block binding to ligands iC3b and fibrinogen.

The mAb binding epitope is formed from P-147, H-148, R-151, K-200, T-203, and L-206 [46]. The first three residues are in the loop and adjacent N-terminal part of α1 helix preceded by residues that form part of the MIDAS metal binding site. The helix and loop undergo an inward (toward the center of the I domain) motion during activation to reposition the MIDAS residue S-144 for ligand binding. The second group of three residues is in the loop connecting α3 and α4 and differs little in position in either closed or open conformation. However, all six residues are adjacent in the $\alpha_M$ I domain structure. The function blocking mAbs CBRM1/21 and CBRM1/22 bind to an overlapping epitope with CBRM1/5 on the MIDAS face. However, neither 1/21 nor 1/22, which were not explicitly selected to bind to activated neutrophils, are activation-specific antibodies, and neither incorporates R-151 in the binding epitope, suggesting that a single amino acid in the epitope is sufficient to account for the conformational selectivity of CBRM1/5 (although other amino acids, which do not differ between mouse and human $\alpha_M$, may contribute to this property as well).

*Class II $\alpha_M$ I Domain mAb Generated by Phage Display* Activation-specific scFv to the αM I domains were obtained using two fully human phage display libraries [47]. The first library was constructed from reverse transcription (RT) of ribonucleic acid (RNA) collected from peripheral blood lymphocytes of five donors and spleen biopsy material of an additional six donors. Variable heavy (VH) and variable light (VL) immunoglobulin domains of antibodies were amplified and randomly reconstructed by overlap extension polymerase chain reaction (PCR). The final library contained ~$2.0 \times 10^9$ clones. The second library (synthetic) was constructed using two human scFv as frameworks (one against estradiol, the second against hepatitis surface B antigen). The H-CDR3 of both scFv was replaced by the sequence C A K/R $X_{4\text{-}7}$ F E/D Y. The VH library contained ~$10^8$ clones. Additional diversity was added by grafting H-CDR-3 sequences from the natural library spleen and peripheral blood lymphocytes (PBLs) complementary deoxyribonucleic acid (cDNA) onto both frameworks to give four additional

libraries of ~$1 \times 10^8$ total clones. The VL library was similarly constructed by replaced L-CDR-3 of the estradiol scFv with the sequence Q V W $X_{4\text{-}7}$ V V and the hepatitis surface B antigen library with the sequence N S R $X_{4\text{-}6}$ V L. A total of ~$6.0 \times 10^7$ clones were obtained from the two libraries. Four additional VL sublibraries were created using PBL and spleen DNA, as was done for the VH, giving an additional ~$2.0 \times 10^7$ clones.

A double-subtraction panning strategy was performed to isolate scFv with the desired properties. The libraries were depleted on resting monocytes and enriched via binding to activated monocytes (which express high affinity $\alpha_M\beta_2$). Next, the library was further enriched for high-affinity binders via incubation with CHO cells transfected with the high-affinity G-F-F-K-R truncation mutant. This step was also subtractive as it depleted phage scFv clones that bound to other activation-specific markers on monocytes. One activation-specific scFv was obtained from the natural library (MAN-1 [monoclonal antibody natural-1]) and two from the synthetic library (MAS-1 [monoclonal synthetic-1] and MAS-2 [monoclonal synthetic-2]).

Activation-specific binding to $\alpha_M\beta_2$ for all three scFv was demonstrated using fluorescent activated flow cytometry (FACS) of CHO cells expressing wild-type (no binding) or G-F-F-K-R truncation mutation (binding) $\alpha_M\beta_2$. In addition, all three antibodies bound activated but not resting monocytes. Furthermore, MAN-1 was shown to inhibit $\alpha_M\beta_2$ binding to immobilized heparin, fibrinogen, and ICAM-1, although not iC3b (either soluble or immobilized) although a nonactivation-specific mAb could block adhesion to all four ligands. MAN-1 also blocked adhesion of PMA-activated but not unstimulated monocytes to immobilized fibrinogen in shear flow conditions. The ability to block some, but not all, $\alpha_M$–ligand interactions supports the mosaic model of ligand recognition, which accounts for the ability of $\alpha_M$ to bind a diverse array of structurally distinct ligands by the presence of distinct (but overlapping) binding sites on the MIDAS face. The ability to block preactivated but not unstimulated (wild-type) $\alpha_M$ binding suggests that the antibody does not efficiently compete with binding in the context of a receptor that rapidly undergoes transition to the active conformation after encountering ligand.

The MAN-1 epitope was located to the I domain by demonstrating the ability of the peptide derived from the fibrinogen binding surface on the I domain to compete with the I domain for mAb binding. However, no dual mAb competition or epitope mapping experiments were performed, and it is unclear if the peptide is structurally homologous to the authentic ligand-binding surface. Furthermore, divalent cation-dependent binding was not demonstrated and presumably is not a characteristic feature of the mAb antigen interaction. The paratope of all three scFv H-CDR-3 was mapped using alanine-scanning mutagenesis. In MAN-1, mutation of the first and last two residues resulted in a small decrease in binding, possibly due to loss of interactions with the flanking framework residues. A more significant decrease was observed with mutation of hydrophobic residues in the center of the loop (W in MAN-1 and MAS-2 and L in MAS-1). This suggests the importance of complementary hydrophobic surfaces in antigen recognition, although it is unclear if H-CDR-3 explicitly encompasses the activation-specific binding surface for αM.

***Some Class II I Domain mAbs Represent Ligand Mimetics*** A subset of this class is made up of *ligand mimetic antibodies*, which are defined by three requisite properties: (1) sharing a common binding site with the authentic ligand, (2) binding is divalent cation dependent, and (3) binding is activation dependent. We recently described AL-57, a ligand mimetic antibody, isolated by phage display to the active conformation of $\alpha_L$. Examples of ligand mimetic antibodies to integrins that do not contain the α I domain are the antihuman $\alpha_{IIb}\beta_3$ PAC-1 [48] and antihuman $\alpha_V\beta_3$ WOW-1 [49]. The H-CDR-3 of PAC-1 contains a R-Y-D sequence that is critical for binding, presumably through similar interactions as the canonical integrin-binding sequence R-G-D. WOW-1 was engineered by replacing the H-CDR-3 of PAC-1 with an integrin-binding loop from the adenovirus penton base protein.

***Class II I Domain mAbs to the $\alpha_L$ I Domain Generated by Phage Display*** mAbs selective for the active conformation of $\alpha_M$ have been obtained both by immunization–hybridoma and library (phage) screening, using either wild-type or high-affinity $\alpha_M\beta_2$ as antigen or bait. By comparison, there are no known mAbs selective for the high-affinity conformation of $\alpha_L$ identified by hybridoma screening. We collaborated with DYAX Inc. to obtain an active conformation-selective mAb to the high-affinity $\alpha_L$ I domain using a human phage display library of $1 \times 10^{10}$ unique Fab clones. (Fab-300). The rationale behind the construction of the library was to create a set of optimized antibody sequences that closely resemble the sequence and length diversity found in natural high-affinity mAbs *after* somatic hypermutation [50]. Specifically, most antibodies selected from libraries derived from unrearranged DNA (naïve libraries) or purely synthetic sequence are low affinity due to the restricted size of the library and limited diversity in both the length of the CDR and in key antigen paratope residues. These mAbs often require protracted affinity maturation protocols, as previously described, to obtain optimal antigen–antibody contact.

The library was constructed as a chimera of human immune cell DNA and synthetic sequence diversified in key positions of H-CDR-1 and H-CDR-2. The VH was constructed on the VH3-23 framework, which is commonly found in rearranged antibodies, and is well expressed and capable of pairing with all light chains. In a structural model of H-CDR-1, positions 31, 33, and 35 (Kabat standard numbering) were found to point toward the antigen-binding site. Each of these three positions was diversified to allow 19 or 20 amino acids (excluding cysteine), imparting greater diversity than that available in the germline sequence. In VH2, there is extensive variability in positions 50, 52, and 52a; amino acids 56 and 58 are often found to vary due to somatic hypermutation. In position 50 and 52, the diversity was limited to tyrosine, arginine, typtophan, valine, glycine, and serine. At position 52, only proline and serine were allowed (these are the highest frequency amino acids at this position). All amino acids except cysteine were allowed at positions 56 and 58.

The variability in sequence and length of H-CDR-3 is difficult to produce using synthetic sequence. Accordingly, the Fab-300 library design employs H-CDR-3 sequences captured from human autoimmune patient B cells expressing IgM. The H-CDR-3 length distribution of 4–26 residues is comparable to that found in naturally isolated antibodies. The sequence diversity was also comparable to authentic mAbs with tyrosine, aspartic acid, glycine, and serine being most common. Complete λ and κ light-chain repertoires were also obtained from autoimmune patient DNA.

A Fab specific for the high-affinity conformation of the $\alpha_L$ I domain was obtained from the Fab-300 library, using the soluble locked open $\alpha_L$ high-affinity mutant as bait [51, 52]. The I domain was randomly biotinylated on lysine residues and presented in solution for capture by streptavidin. The library was depleted using the soluble (inactive) wild-type $\alpha_L$ I domain as decoy bait (negative selection) to avoid selection of clones that bound to both conformations. One clone, AL-57, was identified after three rounds of selection and further characterized.

Using flow cytometry (FACS), we confirmed that AL-57 dose dependently bound to cells expressing $\alpha_L\beta_2$ with the I domain in the locked open conformation, but not wild-type $\alpha_L\beta_2$ [52]. IgG4-AL-57 (used to avoid competing binding with cell surface Fc receptors) bound to activated [10 m*M* Mg(II)/2 m*M* ethylene glycol tetraacetic acid (EGTA)] PBMC but not peripheral blood mononuclear cell (PBMC) in Ca(II) containing buffer; considerable upregulation of AL-57 binding was observed when PBMC was treated with the activating agent PMA. Transient upregulation of AL-57 binding was observed upon treatment of T-lymphocytes with the chemokine CXCL12. The total number of AL-57 epitopes was about 10% of the total number $\alpha_L\beta_2$ (determined using a nonconformational selective antibody) and was comparable to the number of KIM127 epitopes observed in the same conditions.

We sequenced the heavy and light chains of AL-57. The H-CDR-3 is 11 amino acids long and has some homology with the MAS/MAN series of anti-$\alpha_M$ activation-specific antibodies. We performed partial paratope and epitope mapping of AL-57, mutating each aspartic acid residues in each of the six CDR loops to alanine. Mutation of D101 in H-CDR-3 completely abolished AL-57 binding to activated $\alpha_L\beta_2$, while mutation of any other aspartic acid residue in the six CDRs had no effect on integrin binding. In addition, the binding of AL-57 to $\alpha_L$ was completely abrogated in the presence of ethylenediaminetetraacetic acid (EDTA). Taken together, this suggests that AL-57 is a member of a subclass of activation-dependent antibodies that functions as a ligand-mimetic, coordinating a MIDAS-bound Mg(II) with an aspartic acid in H-CDR-3. Significantly, the aspartic acid is part of a short motif, D–F-W conserved in MAN-1 and partially conserved in MAS-1 and MAS-2. However, mutation of the aspartic acid residue in the $\alpha_M$ mAbs had a minor, albeit detectable effect, on binding. Possibly, the $\alpha_M$ conformational selective mAbs have a weak dependence on binding to the MIDAS metal, although no divalent cation dependence for these antibodies was reported. Interestingly, there is a second conserved motif, I-G-S in L-CDR-1 shared between AL-57 and MAN-1.

We used SPR to determine the binding kinetics of AL-57 to soluble high-affinity, intermediate-affinity, and wild-type low-affinity I domain; for comparison, we also studied the kinetics of the conventional, activation-insensitive antibody MHM24. To avoid competing avidity effects, both antibodies were immobilized on the sensor surface over which we flowed high-affinity I domain at various concentrations. The binding of AL-57, but not MHM24, is divalent cation dependent, as we observed no binding of AL-57 to the I domain in the presence of EDTA. Notably, the off rate ($k_{off}$) of AL-57 is markedly slower than that of MHM24 ($k_d = 5.25 \times 10^{-5}$ versus $1.35 \times 10^{-3}\,s^{-1}$). This advantage in dissociation kinetics is offset by an association rate that is 2 orders of magnitude slower ($2.12 \times 10^3$ versus $2.16 \times 10^5\,M^{-1}\,s^{-1}$). Furthermore, while MHM24 is bound to each I domain with comparable affinity, we observed no binding of wild-type I domain to AL-57. Significantly, a mutant I domain that binds to ICAM-1 with micromolar affinity also bind at comparable strength to AL-57. This validates our hypothesis that AL-57 as a ligand mimetic that binds to the cell surface in proportion to the affinity state of cell surface LFA-1.

We compared the binding of soluble multivalent ICAM-1-Fcα to WT LFA-1 activated with Mg/EGTA and CBRLFA1/2 and LFA-1 containing the disulfide locked high-affinity I-domain by FACS in the presence of AL-57 or the blocking, conformation-insensitive antibody MHM24. Both antibodies were capable of antagonizing the binding of multivalent ICAM-1, although the $K_i$ of MHM24 was about twofold lower (WY, SP, NSA, TS, and MS, unpublished observations).

### *Class II mAbs to the β I-Like Domain*

*mAbs to the βA Domain* The βA domain and I domain share a common allosteric mechanism accordingly, or indirectly, via inhibition of critical allosteric motions. A particularly interesting class of mAbs is ligand mimetic to the $\beta_3$ integrins. Representative allosteric and ligand mimetic mAbs are presented below.
